The exact cause of colonic ischemia is unknown. Isolated ischemia without small bowel involvement usually is due to nonocclusive microvascular disease of the colon and not to large vessel (mesenteric artery) occlusion. The primary insult is a low-blood-flow state associated with a variety of factors including congestive heart failure, vasoactive drugs, atherosclerosis, renal failure, and recent cardiac or vascular surgery.38-40 Younger patients may suffer colonic ischemia in the setting of collagen vascular disease, hematologic disorders, long-distance running, or cocaine abuse. The colonic vascular system generally enjoys significant collateral flow, but in some patients this protective mechanism is tenuous, predisposing the affected person to ischemia from low-flow events.41 In addition, colonic arterioles seem to be particularly sensitive to vasoconstrictive influences, and the rapid-growing intestinal mucosa is especially vulnerable to interruptions in blood flow. High intraluminal pressures that normally develop within the colon also can alter intestinal perfusion significantly. Colonic ischemia can occur in any part of the colon, including the rectum, but for unknown reasons it occurs most often in the left colonic segment.

Colonic ischemia represents a spectrum of disease whose manifestations vary with the extent of the ischemic insult. In most cases, the ischemic episode is self-limited and the condition resolves completely with conservative therapy, but in one third of patients, a prolonged or severe insult results in scarring or stricturing of the colon and chronic symptoms.53 If the ischemia is transmural, gangrene and intestinal perforation are possibilities. Chronic mild inflammation results in intermittent symptoms similar to those of IBD.

Clinical Features

The presentation of colonic ischemia may vary but typically involves the acute onset of mild crampy abdominal pain in the left lower quadrant with abdominal distention and almost
always blood in the stool. The typical patient has had recent surgery or has a significant medical illness. Some patients present without pain. Nausea and vomiting can occur with obstruction secondary to a stricture or an ileus. Tenderness over the affected colon may be present but often is not dramatic. Peritoneal findings, fever, and a significantly elevated WBC count suggest gangrenous bowel and perforation. Toxic megacolon is a recognized complication.

## Diagnostic Strategies

No sensitive or specific biochemical markers for colonic ischemia are recognized, although biochemical abnormalities such as elevated serum lactate, phosphate, and alkaline phosphate levels may be present. These abnormalities may be absent in milder disease and often are not observed in more significant disease until after irreversible damage has occurred. A complete blood count to exclude significant anemia and to look for a leukocytosis suggestive of perforation is appropriate. Serum electrolytes should be checked if diarrhea or vomiting has been significant or prolonged. Stool blood and WBCs are common findings in several of the entities that present similarly to colonic ischemia, including IBD and infectious colitis. A positive occult stool guaiac test result should ensure that the patient is eventually evaluated for colonic carcinoma. Unfortunately, the definitive diagnosis of colonic ischemia rarely is made in the ED.

### Plain Radiography

Plain radiographs often show only nonspecific dilated bowel. Findings specific for colonic ischemia occur in only 20% of patients. The classic findings are intraluminal prominences, known as thumbprinting, representing submucosal hemorrhage and swelling. Thumbprinting also can be seen occasionally with other disorders, including IBD, colonic infections, or hemorrhage secondary to anti-coagulants. Other findings consistent with colonic ischemia include wall thickening and ahastral segments. Air in the portal venous system or bowel wall suggests imminent intestinal infarction.

### Barium Enema

Thumbprinting is detected more often by barium enema than by plain radiography, but this study has largely been replaced by colonoscopy.

### Colonoscopy

Colonoscopy with colonic biopsy is the preferred method to diagnose colonic ischemia because it visualizes the abnormal colonic mucosa better than barium enema and affords the opportunity to take biopsy specimens to differentiate between cancer and other non-ischemic causes of colitis. Colonoscopy also can detect necrotic bowel by its distinct cyanotic or black appearance. If colonoscopy is delayed, pathologic changes consistent with colonic ischemia may have already improved or resolved. The diagnosis may be missed on colonoscopy in up to one third of cases.

### Computed Tomography

Although CT does not allow the definitive diagnosis of colonic ischemia, it can exclude other disorders. CT features suggestive of colonic ischemia include thumbprinting, wall thickening, and luminal narrowing and inner wall hypoperfusion (“double halo sign”).

### Angiography

Angiography usually is not helpful in either the diagnosis or the management of colonic ischemia. In most cases, the blood flow defect is at the microvascular level and has resolved by the time the patient presents for evaluation. The exception is the case in which only the ascending colon is affected, suggesting a superior mesenteric artery thrombosis.

### Differential Considerations

The symptoms of colonic ischemia are nonspecific and overlap with those of numerous other disorders including IBD, radiation proctocolitis, and infectious colitis, and of other causes of nonprofuse lower gastrointestinal bleeding. If strictures are present, the possibility of diverticulitis or colon cancer should be considered.

### Management

In the absence of surgical complications, the treatment of colonic ischemia is supportive and includes hospitalization for bowel rest, hydration, and pain management, with some authors recommending antibiotic coverage. NSAIDs are best avoided, as are oral cathartics or bowel preparation regimens that may lead to perforation. Broad-spectrum antibiotics covering bowel flora are indicated for patients with more significant symptoms (see Box 93-5). If colonic ischemia is precipitated by an episode of hypotension, the underlying cause of the hypotension must be sought and treated aggressively, and cardiac output must be maximized. Vasopressors should be avoided to prevent worsening of ischemia, as should steroids, which may facilitate bowel perforation. Colonic distention if present can be relieved acutely through the use of a rectal tube; surgical consultation is recommended in these cases. Decompression of the colon may result in a lowering of transmural pressure and improved colonic perfusion. Sepsis, peritoneal changes, free abdominal air, significant fever, massive bleeding, and a significant leukocytosis suggest bowel necrosis or perforation and should prompt emergent surgical consultation.

### Disposition

Patients with mild symptoms and no significant abdominal tenderness or bleeding can be managed on an outpatient basis and referred for colonoscopy. Stool studies including cultures for bacteria, microscopy to look for ova and parasites, and a Clostridium difficile titer are helpful if the diagnosis is uncertain. Patients with more significant findings, especially if the diagnosis of gangrenous bowel cannot be excluded, require hospitalization. A high mortality rate (60%) is expected for patients undergoing emergent surgery, although deaths before the age of 50 years are rare. Most patients improve without surgical intervention, and only 5% have a recurrence of colonic ischemia. Colectomy usually is curative.

### Radiation Proctocolitis

#### Perspective

Radiation proctocolitis is a common side effect of radiation therapy, occurring in 50 to 75% of patients receiving radiation to the pelvis. The disease has two distinct presentations: acute and chronic. Acute radiation proctocolitis begins during or shortly after a course of radiation therapy, usually is easily diagnosed, and is self-limited. Chronic radiation proctocolitis occurs in 5 to
10% of patients who have had pelvic radiation therapy and typically begins any time up to 2 years after the end of radiation therapy, although onset of clinical manifestations may be delayed beyond 2 years. Some cases have occurred decades later. Patients with more severe acute radiation proctocolitis seem to be prone to chronic proctocolitis. Because of its nonspecific presentation and delayed appearance, the diagnosis of chronic radiation proctocolitis can be challenging. Patients at risk for chronic radiation proctocolitis seem to be those with more severe acute disease.

**Principles of Disease**

Radiation causes tissue injury through the creation of oxygen free radicals, which damage cellular DNA. The faster the growth rate of cells, the more this DNA damage affects their function. For this reason, radiation is an effective treatment for neoplastic disease, but it also damages rapidly growing normal tissue, such as intestinal epithelium. Radiation damage also may adversely affect anal sphincter function, leading to bowel incontinence.

**Acute Radiation Proctocolitis**

Intestinal epithelium normally is sloughed and replaced at a rapid rate. After the start of radiation therapy, growth of replacement epithelium is slowed, but sloughing continues at the preexposure rate. This mismatch leads to gaps in the epithelium, which over time coalesce into ulcerations. In addition, edema and inflammatory changes of the submucosa cause excessive mucus secretion and bleeding. When radiation therapy has ended, the cycle of damage stops, and healing occurs over the next few weeks.

**Chronic Radiation Proctocolitis**

The pathologic mechanism in chronic radiation proctocolitis is entirely different from that in acute radiation proctocolitis. Chronic radiation proctocolitis results from a progressive endarteritis with abnormal tissue collagen deposition. Affected intestine has a decreased microvascular density, with subsequent decreased perfusion. Over time, affected bowel gradually becomes more ischemic, leading to ulceration, scarring, and narrowing of the bowel lumen. Frank necrosis and perforation, although uncommon, can occur. Long-term outcomes in chronic radiation proctocolitis have not been well studied, but it seems that patients in whom fistulas and persistent bleeding strictures develop have the poorest prognosis.

**Clinical Features**

Acute radiation proctocolitis manifests with abdominal pain, bleeding, and tenesmus. Onset during the course of radiation therapy, typically after several treatments, suggests the diagnosis. Fecal urgency and incontinence can be devastating to quality of life.

Chronic radiation proctocolitis has a more insidious onset with a variety of presentations, including ulcerative disease, stricture with or without obstruction, fistulas, and bowel perforation. Symptoms may be similar to those in acute disease, with tenesmus, diarrhea, and urgency. Bleeding can occur but usually is not hemodynamically significant. Decreased caliber of stool with increased straining or constipation suggests a stricture. Fistulas can develop between affected bowel and any adjacent organ, but the most common fistulas are rectovaginal. Some patients may exhibit anal sphincter dysfunction and loss of bowel control. Symptoms tend to have a significant negative impact on the quality of life.

**Diagnostic Strategies**

The diagnosis of acute radiation proctocolitis is made clinically on the basis of the development of typical symptoms in the setting of radiation therapy. Further evaluation usually is not warranted.

Chronic radiation proctocolitis typically is a diagnosis of exclusion. Endoscopy can be suggestive, revealing pale, thickened, and friable mucosa with prominent telangiectasias. Biopsy specimens often show only nonspecific chronic inflammation. In some cases, endoscopy may be technically difficult because of scarring and reduced mobility of the intestine. Barium enema is an acceptable alternative when endoscopy is problematic, so long as bowel perforation is not a concern.

**Differential Considerations**

In chronic radiation proctocolitis, the possibility that symptoms are due to recurrence of the initial malignancy or a new malignancy induced by radiation exposure must be entertained. Symptoms of chronic radiation proctocolitis generally are clinically indistinguishable from those of other causes of bowel inflammation, including inflammatory bowel disease, infectious colitis, and ischemic colitis.

**Management**

Treatment of acute radiation proctocolitis is symptomatic, and a therapeutic plan should be developed in conjunction with the patient’s radiation therapist. Steroid enemas to reduce inflammation and water-absorbing stool softeners to reduce mucus-containing diarrhea are helpful. Reduction of the daily radiation dose also can reduce symptoms significantly.

Chronic radiation proctocolitis treatment also is symptomatic. If rectal involvement is significant, stool softeners, analgesics, anti-inflammatory agents (e.g., sulfasalazine, balsalazide), and sucralfate enemas are helpful. Metronidazole is beneficial when added to anti-inflammatory therapy. Minimally symptomatic strictures can be managed initially with stool softeners and enemas as needed. Some strictures have a reversible edema component, so the extent of narrowing may lessen after treatment. Fistulas and significant strictures generally require surgical repair. Approximately 20% of all patients with chronic radiation injury to the intestinal tract require some type of surgical intervention. Biopsy specimens from ulcerations associated with chronic injury should be obtained to exclude malignancy.

**Disposition**

Suspected perforation mandates emergent surgical consultation, and signs of bowel obstruction should prompt urgent surgical consultation. Unless symptoms are severe, patients with acute or chronic radiation proctocolitis usually can be managed on an outpatient basis under the care of their radiation therapist or gastroenterologist. With acute disease, symptoms typically resolve several weeks after radiation treatments have been completed. Mild chronic disease typically resolves with medical therapy, but more severe symptoms often require aggressive intervention.
New or atypical symptoms in a patient with known IBS should prompt an evaluation for other abdominal pathology.

A new diagnosis of IBS should be left to the primary care setting; the purpose of the ED evaluation is to exclude other abdominal disorders.

A positive result on testing for fecal occult blood should never be assumed to be due to diverticula. An appropriate investigation to exclude malignancy is essential.

Uncomplicated diverticulitis can be diagnosed and treated without imaging in many patients.

An LBO should prompt an evaluation for malignancy.

Gangrene or perforation should be suspected in any patient with persistent unexplained tachycardia, fever, or remarkable abdominal tenderness that is associated with intestinal disease.

Volvulus often appears as a nonspecific large bowel obstruction on plain radiographs.

Although typically a disease of older persons, volvulus can occur at any age.

Intussusception in adults most commonly is associated with a significant cause, often a malignancy.

Intussusception in adults usually manifests as a partial small bowel obstruction and rarely is associated with the classic triad of abdominal pain, mass, and heme-positive stool that is seen in children.

IBD is a lifelong relapsing disorder that can be treated with a variety of therapies. Management decisions are best made in consultation with the physician who will be providing ongoing care for the patient.

Treatment of uncomplicated IBD depends on the clinical classification of disease severity (see Box 93-7).

A new diagnosis of IBD in an elderly patient should be made only after the exclusion of colonic ischemia.

Any evidence of blood in the stool should prompt an evaluation for colon cancer.

Chronic radiation proctocolitis should be considered in any patient with a history of irradiation of the pelvis or abdomen who presents with symptoms of gastrointestinal inflammation. This is true regardless of how long ago the radiation therapy was received.

The references for this chapter can be found online by accessing the accompanying Expert Consult website.
Patients present to the emergency department (ED) with a variety of anorectal complaints. Such problems may be self-limited or may signify the presence of an underlying medical condition. A high degree of sensitivity and a professional demeanor should be maintained in interactions with these patients, who may find it difficult to discuss historical details openly and to describe physical complaints related to this area of the body and its function.

The anorectum marks the end of the alimentary canal. From its beginning at the rectosigmoid junction at the level of the third sacral vertebra (S3), the rectum follows the sacral curvature for 12 to 15 cm and then sharply turns posteriorly and inferiorly at the puborectalis muscle (Fig. 94-1). Here the anal canal begins its 4-cm course to the anal verge, the orifice whereby stool exits the body. It is supported by three muscle groups, the levator ani and the internal and external anal sphincters. Anal valves are located 2 cm proximal to the anal verge at the dentate line. Above the valves are the anal crypts, which contain mucous glands to provide lubrication during defecation. These constitute a nidus for abscess and fistula formation if occluded. Proximal to the crypts are the columns of Morgagni, where the epithelium of the anal canal changes from pink columnar (as in the rectum) to squamous.1-3

The superior, middle, and inferior hemorrhoidal arteries provide the blood supply to the anorectum. They arise from the inferior mesenteric, internal iliac, and internal pudendal arteries, respectively. The superior hemorrhoidal veins drain into the portal system, and the inferior hemorrhoidal veins drain into the caval system. Lymphatic drainage is to the inferior mesenteric nodes above the dentate line and to the inguinal nodes from all areas of the anorectum.2

Sympathetic and parasympathetic nervous systems function together to retain the contents of the rectum until evacuation is desired. Continence is maintained when sympathetic fibers from L1 to L3 (upper rectum) and presacral nerves (lower rectum) inhibit contraction of rectal smooth muscle and L5 fibers cause the internal sphincter to contract. Elimination occurs when parasympathetic fibers from the anterior roots of S2 to S4 cause the rectal wall to contract and the internal sphincter to relax. Voluntary external sphincter control is mediated by motor branches of the pudendal nerve (S2, S3) and the perineal branch of S4. The levator ani is supplied by the pudendal nerve and pelvic branches of S3 to S4 fibers. Sensory perception of rectal distention involves a signal pathway from extramural receptors to parasympathetic fibers from S2 to S4. The abundant sensory nerve endings of the distal anal epithelium perceive sensations that are transmitted by the pudendal nerve.2

Defecation begins as the rectum becomes distended, the internal sphincter relaxes, and stool enters the anal canal. At an appropriate time and place, the external sphincter is relaxed to complete the process of elimination. Sometimes voluntary straining is needed to assist in the passage of stool. When the Valsalva maneuver is performed, the abdominal muscles contract, the rectal angle straightens, and the pelvic floor descends. To postpone defecation, the external sphincter contracts voluntarily. This contraction relaxes the rectal wall and quells the urge to defecate unless there is an underlying sphincter disorder or an overwhelming volume of stool.4

A complete history of anorectal and gastrointestinal (GI) symptoms and the presence of systemic disease elucidates the diagnosis of most anorectal disorders (Box 94-1; Fig. 94-2). Common complaints include bleeding, swelling, pain, itching, and discharge. Standard historical questions about time and circumstances of onset, duration, quality, and exposure to radiation should be asked. Alterations in bowel habits should be noted. These include changes in color, frequency, or consistency of the stool and the presence of straining, flatus, and incontinence of solid or liquid stool. Persons with underlying GI disorders (e.g., Crohn’s disease, cancer, polyps) are predisposed to atypical presentations of anorectal problems. Similarly, those with underlying systemic diseases such as acquired immunodeficiency syndrome (AIDS), cancer, diabetes mellitus, and coagulopathy are prone to develop more serious complications of standard anorectal conditions. Finally, patients should be asked directly about sexual practices involving the anus.5

Rectal Bleeding

The color, amount, and relationship to defecation are important factors in establishing the cause of rectal bleeding. Approximately 10 to 20% of the population experiences rectal bleeding at some time.6 Pain and bright red blood signify anal
fissures or hemorrhoids. Fissure pain is sharp, sudden in onset, and not associated with swelling, whereas pain from a prolapsed or thrombosed hemorrhoid is gnawing, continuous, and of more gradual onset. Painless rectal bleeding occurs with internal hemorrhoids, cancer, or precancerous lesions.

The relationship of bleeding to defecation is important. Visible blood on the toilet paper usually is caused by anal fissures or external hemorrhoids; however, minute quantities can result from any irritating condition. Bright red blood that drips into the toilet bowl or streaks around the stool is caused by internal hemorrhoids. Blood mixed with stool originates proximal to the rectum, whereas melena indicates a very proximal source. Bloody mucus is associated with cancer, inflammatory bowel disease, and proctitis.16
Swelling and Masses

Patients who complain of a swelling near the anus or have the sensation of rectal fullness often list hemorrhoids as their chief complaint. Painful swellings that bleed usually are thrombosed hemorrhoids, but other painful lesions such as abscesses, pilonidal disease, and hidradenitis suppurativa must be considered. Painless, itchy swellings may be caused by condylomata acuminata or secondary syphilis. A mass protruding through the anal orifice may signal rectal prolapse. Perianal and rectal carcinoma should be considered in older persons and those with long-standing anorectal complaints.

Pain and Itching

Severe, episodic anorectal pain that is not associated with bleeding or swelling may represent proctalgia fugax or levator ani syndrome. Perianal itching (pruritus ani) is caused by any lesion that makes hygiene difficult to maintain or may be attributed to certain foods or medications.

Physical Examination

The physical examination should take place in private, respecting the patient’s modesty. The patient can then relax the external sphincter to facilitate a complete examination. The patient is placed in the left lateral decubitus position and covered with a sheet. The buttocks are inspected for dermatologic manifestations of disease and then gently spread apart to expose the anal orifice. Elements of personal hygiene are noted, in addition to anatomic disruptions such as fissures, skin tags, lesions, protruding hemorrhoids, or abscesses. The patient is asked to strain to assess the integrity of the pelvic floor and note prolapse of hemorrhoids or rectal mucosa. Next, a well-lubricated gloved finger is placed flat against the anal opening, exerting gentle pressure until the external sphincter relaxes and allows the finger to enter the anus. Anal sphincter tone can be assessed by asking the patient to squeeze the anal muscles against the examining finger. By sweeping the finger in a circumferential manner, accessible areas of the anorectum can be examined for masses and areas of tenderness. The cervix or prostate is palpated through the rectal wall. A bimanual examination reveals masses and tender areas at the distal portion of the anal canal and perineum. On withdrawal, the contents on the glove can be assessed for frank or occult blood, mucus, or pus.

Direct visualization can be accomplished by anoscopy. With the patient positioned as described, the lubricated anoscope is inserted into the anus with the obturator in place. The obturator is removed to allow a circumferential view of the rectal mucosa. Attention is directed to sites of bleeding, hemorrhoids, masses, or abnormal tissue and finally the dentate line and anal epithelium.

Specific Anorectal Problems

Hemorrhoids

Perspective. When the Philistines defeated the Israelites, the book of I Samuel reports the fate of the avengers: “A deadly panic had seized the whole city, since the hand of God had been very heavy upon it. Those who escaped death were afflicted with hemorrhoids, and the outcry from the city went up to the heavens.” In 1815 the battle of Waterloo marked the defeat of Napoleon’s army. Speculation purports that the great leader suffered from hemorrhoids at the time of his defeat. Hemorrhoidal disease continues to afflict modern humans, with a 4.4% incidence in the U.S. population. Both sexes are affected, and an increased frequency has been documented among whites, rural dwellers, and those of high socioeconomic status.

Principles of Disease. The cause of hemorrhoids is controversial. The anal vascular cushion theory is the most widely accepted. Rather than forming a continuous ring around the anal canal, the submucosa forms three distinct cushions of tissue that are richly supplied with small blood vessels and muscle fibers. Blood supply to these cushions is from the superior rectal artery, with some contribution from the middle and inferior hemorrhoidal arteries, which explains why hemorrhoidal bleeding is bright red. The muscularis submucosa cushions the anal canal during defecation to prevent injury and to aid in fecal continence.

As the supportive tissue deteriorates, often starting in the third decade of life, venous distention, prolapse, bleeding, and thrombosis may occur. Some controversy exists about whether straining and constipation cause these changes by producing venous backflow when intra-abdominal pressure increases. In pregnant women, direct pressure on a hemorrhoidal vein can produce symptomatic hemorrhoids. Up to one third of pregnant women experience hemorrhoids in the last trimester of pregnancy or the postpartum period. An increased incidence of thrombosed hemorrhoids is associated with traumatic deliveries. Some familial predisposition is recognized, but whether this is a result of genetics or acquired factors such as diet is unknown.

Hemorrhoids are not varicose veins; they are normal structures that manifest symptoms when the muscularis submucosa weakens and the anal cushions are displaced distally. Conditions that increase sphincter tone correlate with a higher prevalence of hemorrhoids. Portal hypertension does not cause hemorrhoids. The incidence of symptomatic hemorrhoids is similar in patients with and in those without portal hypertension. Rectal bleeding in patients with portal hypertension may be caused by rectal varices, which are vascular communications between the superior and middle hemorrhoidal veins. A major exception to this observation occurs in the pediatric population; children with portal hypertension are susceptible to hemorrhoidal exacerbations.

Clinical Features. A careful history is needed to confirm the presence of hemorrhoids, because many patients use this term to refer to any perianal condition. Bleeding with defecation is the most common complaint, and unless the hemorrhoids are thrombosed, it usually is painless. Patients report variable amounts of bright red blood on the toilet paper or in the toilet bowl. Many complain of swelling, itching, mucoid discharge, or simply the presence of a moist perianal area. Further history should address recent stool patterns, such as diarrhea or constipation; chronic medical problems, such as portal hypertension or bleeding disorders; and a dietary and family history.

Hemorrhoidal symptoms are exacerbated by frequent bowel movements, prolonged sitting, heavy lifting, and straining while defecating. Although straining is cited as a cause of hemorrhoids, it also may be a result of them when the patient is constipated from delaying defecation because of fear of pain. Physical examination should ascertain the type and degree of hemorrhoids. This can be accomplished by a visual inspection at rest and during straining. Nonprolapsing hemorrhoids can be visualized on anoscopy as a focus of bleeding or as they bulge when the patient is asked to strain while the anoscope is removed. Anoscopy is painful and not useful in cases of prolapsed or thrombosed hemorrhoids.

Hemorrhoids are classified according to their location and severity (Table 94-1). External hemorrhoids originate below the dentate line and receive their blood supply from the inferior
hemorrhoidal plexus. They are covered with modified squamous epithelium (anoderm) and resemble the surrounding skin. Two syndromes are common. First, the veins beneath the skin of the hemorrhoid become dilated and the surrounding subcutaneous tissue becomes engorged, causing swelling or pressure after defecation. Painless, bright red bleeding may occur. Second, the veins can become thrombosed as clots form within them (Fig. 94-3A). This produces acute pain and tenderness to palpation. A bluish discoloration often is noted.

Internal hemorrhoids originate above the dentate line and receive their blood supply from the superior hemorrhoidal plexus (Fig. 94-3B). They are covered with a mucosal surface consisting of transitional or columnar epithelium that looks very different from the surrounding anoderm. They are classified according to severity (Table 94-2). Symptoms and signs range from mild, painless bleeding with defecation to unremitting and debilitating pain. First-degree internal hemorrhoids protrude into the lumen of the anal canal, causing a feeling of fullness. Because the mucosal wall lacks sensory nerve endings, these lesions do not cause pain. Second-degree internal hemorrhoids temporarily prolapse outside the anal canal during defecation but spontaneously return to their normal position at the end of the bowel movement. Both of these are amenable to medical management. Third-degree internal hemorrhoids prolapse spontaneously or during defecation and remain outside the body until they are manually replaced into the anal canal. A throbbing, pressure-like pain may accompany bleeding and subsides when the hemorrhoids are reduced. Fourth-degree internal hemorrhoids cannot be reduced and are permanently prolapsed. Continued prolapse leads to the formation of a thrombus with possible progression to gangrene. Definitive treatment for the intense pain and thrombosis is surgical.

**Management.** The symptoms of nonthrombosed external and nonprolapsing internal hemorrhoids can be ameliorated by the standard regimen—warm water, analgesics, stool softeners, and high-fiber diet (WASH)—aimed at combating the problems that led to their formation (Box 94-2). Anal canal pressures decrease in warm water (40°C). Patients can direct a shower stream at the area for several minutes or take sitz baths. Mild oral analgesic agents reduce the pain. Several over-the-counter preparations are available for the treatment of hemorrhoidal symptoms; however, their use is directed at improved hygiene and temporary symptom relief rather than correcting the condition. The use of topical anesthetics, corticosteroids, astringents (e.g., witch hazel), mineral oils, and cocoa butter is controversial. Prolonged use of topical corticosteroids produces atrophic skin changes and is discouraged. Stool softeners can make the passage of stool easier, to avoid straining. A high-fiber diet (consumption of 20 to 30 g of dietary fiber per day) produces stool that is passed more easily.

Patients with second- or third-degree internal hemorrhoids also benefit from this regimen; however, permanent resolution...
of their symptoms may require surgical intervention (Table 94-3). These patients can be discharged from the ED with the WASH regimen and referred to a surgeon for banding, sclerotherapy, or elective hemorrhoidectomy. Patients with acute, gangrenous, thrombosed fourth-degree internal hemorrhoids should be referred for emergent hemorrhoidectomy.

Acutely thrombosed external hemorrhoids can be excised (not incised and drained) in the ED to provide prompt relief within the first 48 hours after the onset of symptoms (Fig. 94-4). Incision results in incomplete evacuation of the clot, subsequent rebleeding, and swelling. Excision provides long-term relief and prevents subsequent formation of skin tags. If not excised, the thrombosed external hemorrhoid will resolve spontaneously after several days when it ulcerates and leaks the dark accumulated blood, with relief of associated symptoms. Residual skin tags may persist. In the ED setting, this procedure is not commonly performed in pediatric patients, pregnant women, and immunocompromised patients.

Nonsurgical therapy with topical nifedipine (0.3%) with lidocaine (1.5%) gel has been shown to alleviate symptoms when applied twice daily for 2 weeks. The purported effectiveness of this regimen for treatment of thrombosed hemorrhoids is related to the ability of nifedipine to modulate resting sphincter tone and thereby reduce the associated pain and inflammation.

**Anal Fissures**

**Principles of Disease.** The development of an anal fissure is the most common cause of intensely painful rectal bleeding of sudden onset. A superficial tear in the anoderm results when a hard piece of feces is forced through the anus, usually in patients who are constipated. Although anyone can experience an anal fissure, it is most common in the 30- to 50-year age bracket. It is the most commonly encountered anorectal problem in pediatric patients, especially infants. Males and females are affected equally. Most fissures occur along the posterior midline, where the skeletal muscle fibers that encircle the anus are weakest. Anterior midline fissures are more common in women than in men. Fissures that occur elsewhere are more likely to be associated with systemic disease such as leukemia, Crohn’s disease, human immunodeficiency virus (HIV) infection, tuberculosis (TB), or syphilis.

Fissures not treated promptly may become chronic, with development of a classical “fissure triad” of deep ulcer, sentinel pile, and enlarged anal papillae (Fig. 94-5). A sentinel pile forms when the skin at the base of the fissure becomes edematous and hypertrophic. A resolving sentinel pile can form a permanent skin tag and may be associated with a fistulous tract.

**Clinical Features.** The patient complains of a sudden, searing pain during defecation that may be accompanied by a small amount of bright red blood on the stool or on the toilet paper. This is followed by a nagging, burning sensation that lasts for a few hours from internal sphincter spasm. Subsequent bowel movements are excruciating, and the external sphincter can exhibit a reflex spasm. Physical examination must be performed cautiously to avoid further spasm and pain. The depth of the fissure, its orientation to the midline, and the presence of a coexisting sentinel pile or edema are noted. Rectal examination during an acute exacerbation often is impossible because of pain and sphincter spasm.

**Management.** Specific measures for the treatment of anal fissures are summarized in Box 94-3. Treatment using the WASH regimen (see Box 94-2) focuses on eliminating constipation

TREATMENT OF ANAL FISSURES

- WASH regimen*
- Nitroglycerin ointment (0.4%) bid or tid
- Nifedipine gel (0.2%) bid with lidocaine (1.5%)
- Botulinum toxin (Botox) 0.1–0.2 mL
- Anal dilation performed with the patient under general anesthesia
- Surgical excision

*See Box 94-2.

with a bulking agent, stool softener, and high-fiber diet. Warm sitz baths and limited use of topical anesthetics may be helpful. Parental encouragement to pediatric patients helps prevent encopresis that can result from a fear of painful bowel movements. Most acute, uncomplicated fissures resolve in 2 to 4 weeks. For adult patients who suffer from chronic anal fissures, application of various topical agents aimed at reducing sphincter pressures has been effective.26,27 Hyperbaric oxygen has been used successfully for adjunctive therapy.28 Application of lidocaine ointment is effective in treating chronic anal fissures. In addition, nitroglycerin ointment applied topically to the anoderm two or three times daily has been shown to relieve the pain from anal fissures. Although it was not associated with more rapid healing, patients receiving this therapy reported a higher level of comfort during the healing process. The typical side effect of a vasodilatory headache may be experienced by some patients.29,30

Nifedipine gel (0.2%) in combination with lidocaine (1.5%) applied to the anal area twice daily is effective in promoting healing and reducing discomfort in the management of anal fissures. The mechanism of healing is thought to be the reduction of anal canal pressures by local calcium channel blockers.31-33 When the efficacy of calcium channel blockers was compared directly with that of topical nitrates, the rates of healing and recurrence were similar; however, the incidence of side effects was lower in one study.34 Injection of botulinum toxin by colorectal surgeons (2.5 to 5.0 Units, 0.1 to 0.2 mL of Botox preparation) is effective in relaxing the sphincter tone by inhibiting acetylcholinesterase release but may cause temporary, reversible fecal incontinence.32,33 Injection into the external (rather than internal) sphincter muscles may reduce this undesirable side effect. It has not yet been studied as a primary treatment in the ED or primary care setting. In comparison with the topical treatments, botulinum toxin is superior in its rate of permanent healing;35 however, the first line of therapy is still topical agents because of their cost, ease of application, and benign side effect profiles.36 Long-term treatment of recurrent fissures focuses on reducing resting anal pressures and may require anal dilation performed with the patient under anesthesia or surgical correction to reduce the tone of the internal sphincter.29,35

Abscesses and Fistulas

Principles of Disease. Anorectal abscesses and fistulas are most common in adults 30 to 50 years of age, and men are afflicted more often than women.1,41 An increased incidence in infants (85% in male babies) has been reported to be associated with congenital abnormalities.42-44

One probable cause of anorectal abscesses is occlusion of the ducts of the mucus-producing anal glands at the base of the anal crypts (the cryptoglandular theory). Abscesses also are caused by inflammatory bowel disease, trauma, cancer, radiation injury, and infection (TB, lymphogranuloma venereum, actinomycosis).1,41,43 Common causative bacteria are Staphylococcus aureus, Escherichia coli, Streptococcus, Proteus, and Bacteroides.

Management

General Approach. The various types of abscesses are the acute manifestations of a continuum of anorectal infections, whereas fistulas are the chronic sequelae. Symptoms vary depending on the site of infection, but incision and drainage constitute the curative treatment in all cases (Table 94-4). Delay of medical management may allow extension of the infection and eventual compromise of the sphincter mechanism.45 Adjunctive antimicrobial therapy is indicated in patients who are immunocompromised or diabetic or have valvular heart disease. Tetanus immunization status should be verified. The sites of anorectal abscess formation are depicted in Figure 94-6. The difficulty in diagnosis is that pain often precedes physical findings of a mass or fluctuance. Approximately 34% of patients with AIDS develop anorectal abscesses and fistulas. In addition to the usual organisms, many are infected with opportunistic ones. HIV-infected patients appear to be more likely than their seronegative cohorts to have an incomplete fistulous tract. This condition prevents adequate spontaneous drainage, highlighting the urgency of treating these patients promptly. A small incision is desirable when possible because wound healing in general may be impaired.

Treatment of Specific Abscesses

Perirectal and Perianal Abscesses. Perirectal and perianal abscesses are the most common (40 to 45%) and produce painful swelling at the anal verge that is worsened by defecating or sitting. Most patients are afebrile. Physical examination reveals localized tenderness, erythema, swelling, and fluctuance. If tolerated, anoscopy may reveal pus in the anal crypts. ED management by incision and drainage with same-day discharge is possible in patients who do not have comorbidity (e.g., dia-

Postanal Abscess. Postanal abscesses are uncommon and occur posterior to the rectum, deep to the external sphincter, and inferior to the levator ani. Patients complain of severe rectal discomfort and coccygeal pain. They usually are febrile and have continuous pain that does not change with position. Rectal examination is painful, but anal drainage is rare. Many of these abscesses are missed on initial presentation, and the patient may be misdiagnosed as having lumbosacral strain, proctalgia fugax, sciatica, or coccygodynia. Patients often return in a few days with an abscess draining at the skin. Treatment is surgical.1

Horseshoe Abscess. Occasionally, a large, communicating, horseshoe-shaped abscess forms in the ischiorectal, intersphincteric, or supralever space. Surgical management is necessary.

Necrotizing Infection. A delay in management of an anorectal abscess may lead to the destruction of tissue, especially in diabetic or immunocompromised patients. Widespread cellulitis, necrotic tissue, and gas on radiography suggest the possibility of necrotizing fasciitis, Fournier's gangrene, or tetanus. Wide surgical débridement, broad-spectrum antibiotics with anaerobic coverage, and tetanus prophylaxis are required.1

Treatment of Fistulas. A fistula (Latin for “pipe”) is a connection between two epithelium-lined surfaces. Anorectal fistulas develop in 50 to 67% of patients with ischiorectal abscesses.45 Other causes include Crohn’s disease, trauma, foreign body reactions, TB, and cancer. Evidence to support these diagnoses should be sought because the anorectal complaint may be the presenting symptom of the fistula. Patients notice a recurrent or persistent perianal discharge that becomes painful when one of the openings becomes occluded. Bidigital rectal examination may reveal a tract in the perineum or canal. Probing of fistulous tracts is not recommended because the danger of creating a new tract outweighs the benefit of identifying the path of the existing fistula. Diagnostic evaluation may include intrarectal ultrasonography, fistulography with radiopaque dye, or radiolabeled white cell scanning during surgery.41,43,48 Spontaneous resolution of fistula-in-ano is rare. Symptoms resolve when antibiotics are administered (e.g., ciprofloxacin, metronidazole) but commonly return as soon as therapy is discontinued. Other nonsurgical treatments that are effective for some patients, especially those with Crohn’s disease, are administration of infliximab, a monoclonal antibody, or cyclosporine and hyperbaric oxygen therapy.45 Because most fistulas produce recurrent abscesses if untreated, potentially leading to sphincter dysfunction, patients should be referred for surgical management. Immediate or delayed fistulotomy, fistulectomy, or repair with fibrin glue may be done.41,48,49
Pilonidal Disease

Principles of Disease. Little nests of hair in the sacrococcygeal area were first described in 1847 by Anderson (Latin pilus, “hair”; nidus, “nest”), who originally believed the lesions to be scrofula. More than 150 years later, physicians have yet to agree on the cause and best mode of treatment. Pilonidal abscesses and subsequent sinus tracts afflict young adults with a 4:1 male predominance and are more common in obese and hirsute persons. The disease is rare in people older than 40 years, even among those who were afflicted in their youth. The lesions arise in the midline of the sacrococcygeal area in the natal cleft and should not be confused with anal fistulas, perirectal abscesses, hidradenitis suppurativa, or granulomatous diseases (syphilis, TB). Much of the current understanding of pilonidal disease comes from the experience in World War II, when the condition was rampant among jeep drivers and was therefore dubbed “jeep-driver's disease.”

The debate between congenital predisposition and acquired disease seems to favor the latter. This theory asserts that bacteria enter the usually sterile hair follicle and produce inflammation and edema, thereby occluding the opening to the skin surface. The contents expand until the hair follicle ruptures, and the material spreads into the subcutaneous fatty tissue, where a foreign body reaction leads to abscess formation. The purulent material subsequently tracks cephalad and drains to the skin through a laterally displaced, epithelialized tract. Diagnosis is made by establishing the presence of a painful, fluctuant area in the presacral skin. In chronic or recurrent disease, visible or palpable tracts of 2- to 5-cm length may be identified with openings approximately 5 cm above the anus. These sinuses usually contain hairs and cellular debris.

Management. Treatment options vary, ranging from conservative therapy to extensive surgical management. Antibiotics can supplement surgical drainage in cases accompanied by cellulitis but are not effective as the primary mode of treatment. ED management of pilonidal disease involves drainage of the acute abscess for relief of symptoms. To prevent reaccumulation of debris and to minimize inflammation in the midline, a longitudinal incision lateral to the sacral midline should be made. To decrease the usual 40% recurrence rate, the patient can be referred for follicle removal and unroofing of sinus tracts after the acute inflammation subsides (usually 1 week). An alternate noninvasive strategy of shaving the hairs in the natal cleft every 3 weeks has been reported. For patients whose disease is recalcitrant, unroofing and marsupialization or wide excision techniques are used.

Hidradenitis Suppurativa

Perianal hidradenitis suppurativa is an infection of the apocrine glands. It is most common in young adults and is related to poor skin hygiene, hyperhidrosis, obesity, acne, diabetes mellitus, and smoking. The condition commonly is misdiagnosed as pilonidal disease or fistula-in-ano. Other considerations in the differential diagnosis include sebaceous cysts, furuncles, granulomas (from TB or syphilis), and Crohn’s disease. Occluded apocrine ducts may be infected with strains of Staphylococcus, Streptococcus, E. coli, or Proteus. Extension through the dermis spreads the infection to neighboring ducts, and a network of sinus tracts forms. This cycle leads to extensive scarring.

Patients complain of a pustule in the perianal area, which may be associated with fever, leukocytosis, and malaise. One or more tender pustules may drain pus and be surrounded by cellulitis. Local lymphadenopathy is common. Treatment begins with careful attention to perianal hygiene, warm compresses, and broad-spectrum antibiotics. Recently, infliximab has been found to be effective, resulting in rapid clinical improvement. Drainage of isolated lesions may provide symptomatic relief, but the recurrence rate approaches 40%. Referral to a surgeon for wide excision of tissue involved in advanced chronic disease may be necessary.

Proctalgia

Perspective. Anorectal pain (proctalgia) that does not arise from one of the organic disorders described earlier can be severe and difficult to treat. The two most common causes are levator ani syndrome and proctalgia fugax. These disorders can be distinguished by their patterns of affliction. Other causes of pelvic pain, such as tumors, cauda equina syndrome, and endometriosis, must be considered.

Levator Ani Syndrome

A constant, dull pressure in the sacrococcygeal region that is precipitated by defecation or prolonged periods of sitting suggests levator ani syndrome. The patient usually has tenderness of the levator muscles, which may be firmly contracted on examination. It affects both men and women. No standard treatment regimen has been studied, but anecdotal reports indicate that sitz baths, levator ani muscle massage, and muscle relaxants can provide some relief.

Proctalgia Fugax

Proctalgia fugax is an intensely painful spasm in the rectal area that begins abruptly and lasts for several minutes. It is attributed to a sudden spasm of the levator muscle complex or the sigmoid colon. People who frequently visit the toilet are at greatest risk, and women are more commonly affected than men. A psychogenic predisposition is described by Pilling and colleagues, who found that professionals, managers, and perfectionists are more likely to be afflicted.

Proctalgia fugax can begin abruptly during sleep, defecation, urination, or intercourse. The nature of the pain has been compared to a “charley horse.” It lasts less than 30 minutes and may radiate to the coccyx or perineum. Symptoms during recurrent episodes are consistent for the affected person, and each patient has a unique constellation of symptoms. Treatment often is unrewarding, but recommendations include bowel cleansing regimens, upward manual pressure on the anus, diazepam, and topical nitrates.

Fecal Incontinence

Perspective. Fecal incontinence is an embarrassing condition that affects parous women, elderly persons, and patients with a variety of neurologic or traumatic disorders. The pathophysiology involves disruption of the delicate balance among the pelvic floor muscles, sphincters, and anorectal sensation. Complete incontinence is the inability to control passage of solid feces. Partial incontinence is characterized by loss of control of the passage of flatus or liquid feces.

Principles of Disease. Multiple causes of fecal incontinence have been described (Box 94-4). Injury to muscles and nerves may result from accidental trauma or surgery for anorectal disorders. Similarly, injury or stretching during childbirth can cause immediate or delayed problems. Spinal cord and cauda equina lesions and the autonomic neuropathy of diabetes mellitus can cause progressive incontinence. Liquid feces may seep around tumors or foreign bodies of the rectum or anal
The physical examination should address the causes of fecal incontinence. Patients with pruritus ani complain of an itchy perianal area. In otherwise healthy children, sexual abuse involving the anus must be considered. In otherwise healthy children, sexual abuse involving the anus must be considered.

Clinical Features. The physical examination should address the local and systemic factors described previously. The anorectum should be assessed for masses, hemorrhoids, evidence of previous surgery, and neuromuscular function. The anocutaneous reflex, or “anal wink,” is elicited by touching the skin near the anus with a pin and observing the resulting constriction. Sphincter function is assessed by asking the patient to “squeeze” the examiner’s finger.

Management. The approach to management of fecal incontinence depends on the cause. Structural and inflammatory conditions may be diagnosed with anoscopy. In cases of transient incontinence caused by diarrhea, a high-fiber diet along with brief therapy with loperamide or opioids has been shown to solidify stool and enhance rectal compliance. Neuromuscular causes of fecal incontinence can be diagnosed by anorectal physiologic testing. In addition to conservative treatment measures described for transient incontinence, Kegel exercises, biofeedback training, or surgical repair may be necessary.

**Pruritus Ani**

Principles of Disease. Patients with pruritus ani complain of an uncontrollable urge to scratch the perianal area. Approximately 1 to 5% of the population seek medical attention for this condition during their lifetime. Others rely on self-treatment to soothe less severe symptoms. The period of peak incidence is during the fifth and sixth decades of life, and it occurs more often in men. The condition is more common in the summer months and is more noticeable at night. The sensation of itching arises when the richly innervated perianal skin becomes irritated. Patients scratch vigorously in an effort to relieve the itching, creating a vicious circle that results in greater irritation and excoriation. The causes of pruritus ani are summarized in Box 94-5.

The most common cause is the presence of feces on the perianal skin. Conditions ranging from poor personal hygiene to anatomic disorders of the anorectum allow feces to accumulate in the area. Patients may not clean the area thoroughly after defecation. Disruptions in the anorectal anatomy can lead to uncontrollable fecal accumulation on the perianal skin. Obesity, deep perianal clefts, copious hair, hemorrhoids, post-hemorrhoidal skin tags, rectal mucosal prolapse, anal fissures, and fistulas make the area difficult to clean effectively. Decreased air circulation from wearing tight pants or undergarments of synthetic “nonbreathable” fabric may exacerbate symptoms.

hydrocortisone) augment the irritant quality of the feces by altering its pH. Perfumed soaps and drugs, especially local anesthetic creams and ointments, can produce a contact dermatitis. Prolonged use of hemorrhoidal preparations containing local anesthetic and topical corticosteroid can exacerbate the symptoms. Other dermatologic conditions include psoriasis, seborrhea, lichen simplex, and lichen sclerosus.

Systemic diseases and local infections can produce perianal itching. Chronic renal failure, diabetes mellitus, thyrotoxicosis, myxedema, polycythemia vera, deficiency of iron or vitamin A or D, and certain cancers (Bowen’s disease, Paget’s disease, Hodgkin’s disease) are systemic causes. Local conditions include pinworms (Enterobius vermicularis infection), scabies (Sarcoptes scabiei infection), bacterial or fungal infections, and dermatologic manifestations of sexually transmitted diseases (STDs) (e.g., syphilis or herpes simplex virus [HSV], cytomegalovirus, or human papillomavirus infection).

Management. A careful history and physical examination can identify the etiology of pruritus ani. Important considerations include hygienic care of the anus, coexisting anorectal or systemic conditions, diet, and sexual practices.72

Pinworms can be identified by applying transparent tape to the perianal area and attaching it to a glass slide. Visualization of eggs under the low-power objective of a microscope confirms the diagnosis. The first-line agent is mebendazole (Vermox), 100 mg orally. An alternative agent is pyrantel pamoate (Antiminth) 1 g orally (11 mg/kg, to a maximum of 1 g for pediatric patients). The dose of either may need to be repeated in 2 weeks. Scabies and pediculosis pubis should be treated with 1% lindane lotion or 5% permethrin cream. Dermatitis caused by a fungal infection is characterized by sharply demarcated borders and is treated with clotrimazole or nystatin cream. Definitive treatment of concomitant anorectal conditions (e.g., fissures, fistulas, hemorrhoids, skin tags, rectal prolapse) can prevent recurrence of pruritus ani.

Underlying systemic diseases that have perianal manifestations should be treated. Education on personal hygiene is of the utmost importance. Patients should be instructed to clean the area thoroughly with lukewarm water after each bowel movement and pat (rather than rub) it dry with a tissue or towel that is free of chemical irritants. Loose-fitting underwear and exposure to fresh air may aid in alleviating symptoms. The treatment of acute dermatitis includes a short course of topical corticosteroids,24 calamine lotion, and systemic antihistamines.72 Some success with topical application of capsaicin cream has been reported.71,74 Prevention of recurrent bouts of pruritus ani requires compliance with impeccable anal hygiene and minimizing the factors that caused the initial exacerbation.

SEXUALLY TRANSMITTED DISEASES AND PROCTITIS

General Approach

The incidence of STDs has increased in the past few decades, and anorectal transmission is of particular concern in the patient with HIV infection. For patients who are sexually active, the history should ascertain whether sexual practices involve anal penetration and whether condoms are used. As a means of public health prevention of disease and patient safety, education regarding transmission of STDs and the efficacy of barrier methods is important.75 Semen has a concentrated viral load, and the damaged epithelium of ulcerated anoderm makes an easy portal for entry of the virus.76

The constellation of infectious diseases that afflicts the anus, rectum, and colon was historically referred to as “gay bowel syndrome,” although it also affects women who engage in anal intercourse. In the past decade, a resurgence of syphilis, gonorrhea, and chlamydial infection has been documented among men who have sex with men. For this reason, more frequent STD screening is indicated in this population.75 A summary of common infections and treatment guidelines is presented in Table 94-5.

Surgical repair for benign anorectal conditions in HIV-positive patients should be undertaken early in the course of the disease, when potential wound healing and overall patient health are at their best.76 Empirical therapy is indicated for patients who have recently practiced anal-receptive intercourse and present with a rectal discharge. The recommended regimen is ceftriaxone 125 mg intramuscularly for one dose plus doxycycline 100 mg twice a day orally for 7 days.75,77 All patients with anorectal infections should be referred for HIV testing. The possibility of sexual assault should be considered and managed appropriately.75,78,79 The health care provider should report STDs and new diagnoses of HIV infection in accordance with state and local health department regulations.75

Treatment of Specific Sexually Transmitted Diseases

Gonorrhea

Gonorrhea is caused by the gram-negative diplococcus Neisseria gonorrhoeae and is most prevalent in young adults. Routine screening in homosexual men reveals that 55% have been infected, although not all experience symptoms.76 It is postulated that gonorrhea is a cofactor for transmission of HIV.80 Proctitis (inflammation of the rectum) results from anal intercourse or autoinoculation from vaginal secretions and becomes symptomatic after a 5- to 7-day incubation period. Symptomatic patients complain of pruritus ani, tenesmus, and bloody or thick, purulent yellow drainage. Anoscopic reveals proctitis and mucus in the anal crypts. Recovery of the organism directly from the crypts doubles the likelihood of identifying the organism on Gram stain. Only water should be used to lubricate the anoscope, because many lubricants contain an antibacterial agent. Signs and symptoms of disseminated gonococcal infection may include arthritis, skin lesions, perihepatitis, endocarditis, and meningitis.74

Chlamydial Infection and Lymphogranuloma Venereum

Infection with Chlamydia trachomatis, an intracellular organism that is endemic to the tropics, is the most common STD in the United States.75,82 It causes proctitis in people whose sexual practices include anal intercourse or oral-anal contact. Common signs and symptoms include mucoid or bloody rectal discharge, tenesmus, and burning. Some people are asymptomatic carriers of the organism. Lymphogranuloma venereum is a more serious manifestation caused by specific strains of C. trachomatis that starts as a painful anal or perianal ulceration. Prominent unilateral lymph nodes coalesce to form a bubo, which must be distinguished from a granuloma of secondary syphilis. Patients often have systemic complaints of fever and malaise. Anoscopic examination reveals an erythematous, friable mucosa. Rectal cultures generally are unreliable because the organism is intracellular. Diagnosis is best achieved by immunofluorescent antibody testing. In its final stage, rectal strictures and rectovaginal fistulas may form.66
Herpes Simplex Virus Infection

Herpes proctitis is caused by both HSV-1 and HSV-2, but HSV-2 is responsible for approximately 90% of cases. The seroprevalence of HSV-2 in the HIV-positive population is 95%. Syphilis is caused by the spirochete Treponema pallidum, the motile spirochete responsible for the disease. The number of reported cases of syphilis is increasing. For pregnant women or those allergic to tetracyclines,

Part III  ■  Medicine and Surgery / Section Five  ■  Gastrointestinal System

Syphilis can be confused with lymphoma, but the diagnosis can be made by visualizing spirochetes on darkfield microscopy from scrapings taken from the base of the ulcer. Serologic testing is useful several weeks after the appearance of the chancre. Treponemal tests such as the fluorescent treponemal antibody test yield a positive result earlier than does the Venereal Disease Research Laboratory (VDRL) or rapid plasma reagin (nontreponemal) test. Patients infected with HIV may take longer to test positive, and in some cases test results remain negative despite infection. Patients with AIDS have a high incidence of neurosyphilis regardless of the stage of syphilis at the time they seek treatment.

In some patients the chancre goes unnoticed, and they are seen initially with secondary syphilis, marked by the appearance of a maculopapular rash that characteristically involves the palms and soles, or of condyloma lata. The latter is a spirochete-laden, weeping, verrucous lesion in the perianal area that emits a foul odor. It is easily distinguishable from condyloma acuminatum, which has a drier, more keratinized appearance. Serologic testing results usually are positive. Tertiary syphilis is rare but may manifest as a rectal gumma with severe perianal pain and paralysis of the sphincters, which may initially cause it to be mistaken for cancer.

Chancroid

Chancroid is caused by the gram-negative bacillus Haemophilus ducreyi and begins as an inflammatory pustule or macule that ruptures to form an irregularly shaped ulcer. In several days, painful inguinal adenitis develops. Chancroid often is a diagnosis of exclusion. All antimicrobial therapy regimens, especially single-dose ceftriaxone, are less effective in HIV-positive patients.

Condyloma Acuminatum

Condyloma acuminatum, the most commonly encountered anorectal STD, is caused by human papillomavirus. These lesions, also called genital warts, most often are found in homosexual men but can be seen in heterosexual men, women, and children. The mode of transmission is primarily through sexual intercourse, but transmission can occur through close personal contact, as often happens in pediatric cases in which an infected person is changing a diaper and transmits the virus to the infant because of poor hand-washing techniques. It is incumbent upon the evaluating physician to consider sexual abuse in such cases. Because one half of HIV-positive patients have anal warts, HIV testing is recommended in patients with this diagnosis.

The pink-to-gray warts are a result of hyperplastic epithelial growth and appear as vegetative papilliform growths (Fig. 94-7). They may coalesce to form a massive patch that obscures the anal verge. Many patients are asymptomatic or complain of pruritus ani, “hemorrhoid,” or bleeding. Evaluation should include anoscopy because the warts often grow within the anal canal. Failure to treat the internal lesions results in recurrence. The differential diagnosis includes the condyloma latum of secondary syphilis, which is flatter and more moist in appearance. Squamous cell carcinoma also should be considered if the lesions are indurated. Progression to intraepithelial neoplasia has been reported to be related to the level of immunosuppression.

Outpatient treatment with 0.5% podofilox solution or gel is limited to mild cases involving external lesions. The podofilox should be applied twice daily for 3 days followed by 4 days without therapy. This may be repeated for a total of four cycles per incidence. An alternative patient-applied regimen is imiquimod 5% cream applied at bedtime three times per week for up to 16 weeks. Multiple applications of podophyllin resin, cryotherapy, intralesional interferon, or laser surgery by the physician may be required.

Ulcerative Lesions in the Patient with HIV Infection

The practice of anal intercourse has led to a proliferation of anorectal STDs. Most patients who are HIV-seropositive have current or past infection with an STD, which may be the initial reason for seeking medical attention. One third of anorectal complaints in this population fall into three categories: (1) routine proctologic conditions as seen in the general population, (2) STDs, and (3) opportunistic infections (Box 94-6). The treatment of routine conditions and common STDs is similar to that in other patients except that wound healing may be slower in HIV-infected patients.

In immunocompromised patients, the differential diagnosis of ulcerative anorectal lesions should include opportunistic infections, lymphoma, and Kaposi’s sarcoma. In approximately 10% of patients with AIDS, cytomegalovirus proctitis with tenesmus, diarrhea, and weight loss develops. The only clue may be the presence of an anal ulcer that may be indistinguishable from a fissure. Further diagnostic testing and treatment are required. Patients with AIDS often exhibit idiopathic anal ulcerations with pain and bleeding. Before this diagnosis is made, other possible causes of the lesions must be considered (see Box 94-6). Symptomatic relief can often be achieved by the WASH regimen (Box 94-2), but recalcitrant lesions may require surgical excision.
Radiation Proctitis

Radiation-induced injury caused by treatment of gynecologic, urologic, and GI malignancies occurs most commonly in the rectum. Because of the ability to deliver localized radiation to organs in the pelvis, the dose of radiation for treatment of malignancies often is higher than for treatment of other forms of cancer. Immediate radiation proctitis usually is self-limited and responds to symptomatic treatment. Delayed radiation proctitis can manifest up to 2 years after the exposure to radiation and may predispose the patient to subsequent rectal malignancies as a result of damage to DNA.

Signs and symptoms of radiation proctitis include bleeding ranging in severity from spotting to hemorrhage, tenesmus, diarrhea, pain, fistula-in-ano, and rectal strictures. Diagnosis is achieved by rectal mucosal biopsy, a procedure best performed with the patient under sedation or anesthesia.

Treatment regimens include the use of anti-inflammatory agents, botulinum toxin injection, enemas with short-chain fatty acids, oral sucralfate therapy, hyperbaric oxygen therapy, and sclerosing therapy. Supportive therapy can be given for symptoms that the individual patient experiences.

Prolapse

Rectal prolapse, or procidentia, is a disease of persons at the extremes of age. Prolapse is complete if all bowel layers protrude and incomplete if only the mucosal layer is involved. In adults, complete procidentia is most common among older women with a history of excessive straining while defecating. The cause is a laxity of attachment structures, and the rectal prolapse often is accompanied by uterine prolapse or cystocele. Patients complain of an anal mass that protrudes during defecation, coughing, or sneezing. Findings may include fecal incontinence, bloody or mucoid discharge, and a foul odor. In some cases the patient is able to reduce the prolapse manually, while in others the tissue becomes edematous and they present with a red, ulcerated mass protruding from the anus (Fig. 94-8). Sphincter tone may be weakened. Reduction should be attempted; when this is successful, the patient should be discharged with agents to relieve constipation. Surgical repair often is necessary.

In children up to 4 years of age, procidentia often is associated with chronic constipation or diarrheal disease. However, it may herald the presence of malnutrition, parasitic infection, or cystic fibrosis. Children usually have a mucosal prolapse. The parent reports protrusion during defecation with small amounts of mucus or blood. This condition must be distinguished from a protruding juvenile polyp and intussusception. Gentle reduction may be attempted. Conservative medical management aimed at the cause of procidentia often is successful because of the self-limited nature of the condition in children. Increasing the dietary fiber and fluid intake frequently is successful as a first line of therapy.

Anorectal Foreign Bodies

Perspective. The incidence of anorectal foreign bodies is on the rise with the increasing popularity of the anus for sexual gratification. Rectal foreign bodies also are found in children, psychiatric patients, and victims of assault or as a result of iatrogenic injury. Most objects are introduced directly into the anus, but some become lodged there after oral ingestion. It is important to identify and remove foreign bodies to prevent mucosal lacerations, intestinal obstruction, sepsis, and parotiditis.

In many cases, removal can be done safely in the ED.

Clinical Features

Objects Inserted Into the Anus. In a few cases, the foreign body is introduced iatrogenically. The two most common foreign bodies in this category are the enema tip and the broken rectal thermometer. In most cases, however, the foreign body is placed deliberately by the patient or a partner for medicinal or sexual purposes. Objects that are commonly retrieved include fruits and vegetables; household items, especially those whose dimensions resemble the penis; and those purchased specifically with an anal erotic intent. By the time patients arrive at the ED, sometimes days after the introduction of the foreign body, they have most likely tried to remove it at home. The history of the injury often is reluctantly given or is vague and inconsistent. The initial ED evaluation, conducted in a nonjudgmental manner, attempts to ascertain the type of foreign body involved, how long it has been there, what attempts have been made to remove it, and whether the patient has fever, abdominal pain, or rectal bleeding. The possibility of assault should always be considered.
Physical examination of the anorectum begins with an external examination for signs of trauma followed by digital rectal examination and anoscopy, which may reveal the foreign body, a lax sphincter, or a mucosal injury. Abdominal examination may demonstrate signs of perforation or obstruction. The foreign body may be visible on abdominal radiographs, or its presence may be inferred by a nonspecific gas pattern, free air, or signs of intestinal obstruction. If perforation is suspected, water-soluble contrast material can be introduced to delineate radiolucent foreign bodies.

**Orally Ingested Foreign Bodies.** Some foreign bodies that are ingested orally, especially toothpicks and fish or chicken bones, pass through the GI tract and subsequently become lodged in the rectum or anal crypts. Patients at highest risk for ingested foreign bodies are children, especially those in the first 2 years of life; psychiatric patients; and body packers who ingest condoms containing drugs.

**Management.** Optimal treatment depends on the location and type of object found. Generally, objects that are soft and low-lying (less than 10 cm from the anal verge) can be removed safely in the ED. Large, hard, fragile objects and those that have migrated proximally are difficult to remove without anal dilation and instrumentation to assist in the passage through the sacral curve and sphincters. These are best performed with the patient under general anesthesia. As a rule, however, the patient should remain awake to assist in expulsion by performing the Valsalva maneuver at the appropriate time, and premedication with a benzodiazepine is helpful to relax both the sphincter and the patient. With the patient in the lithotomy position, suprapubic pressure can assist in removal (Fig. 94-9). Other positions may be more appropriate for a particular foreign body.

Several methods are effective for removal. The easiest is to grasp an edge of the foreign body with forceps and apply traction while the patient bears down. Most foreign bodies in the rectum do not have a convenient place to grasp, and other methods are needed. A Foley catheter can be placed beside the foreign body and the balloon inflated proximal to it (Fig. 94-10). This breaks the suction of the rectal wall mucosa and provides a way to guide the object out of the rectal vault. Hollow objects may be filled with plaster of Paris, with an inset, inflated Foley catheter to be used as a handle.

Other creative ways to remove foreign bodies in the ED have been successful, and an individualized strategy for each patient is essential. After the removal of the foreign body, all patients should undergo sigmoidoscopy to look for mucosal tears and perforations. Discharge instructions should warn the patient about signs and symptoms of perforation, peritonitis, and sepsis.

**KEY CONCEPTS**

- Patients who seek treatment for nonspecific anorectal complaints should be evaluated for the presence of underlying systemic disease (e.g., cancer, diabetes mellitus, immunodeficiency) because disorders of the anus may herald associated conditions.
- Patients with any STD should be evaluated for HIV infection and questioned about the use of the anus for sexual purposes.
- Anorectal conditions can be differentiated according to an algorithm (see Fig. 94-2) that addresses the presence or absence of pain, bleeding, swelling, and pruritus, in combination with an assessment of the patient's overall health.
- Most anorectal conditions can be symptomatically improved by adhering to the WASH regimen (warm water, analgesics, stool softeners, high-fiber diet).

EVALUATION OF RENAL FUNCTION

The evaluation of renal disease in the emergency department (ED) requires the intelligent use of urinalysis, serum and urine chemical determinations, and renal imaging studies to assess the degree of renal dysfunction and to take the first steps in determining its cause.

Diagnostic Strategies

Urine Volume

Because urine flow does not diminish until the glomerular filtration rate (GFR) is sharply decreased, urine volume is a poor indicator of renal dysfunction. In fact, urine volume often increases as concentrating ability is lost with advancing renal dysfunction; patients with renal failure typically produce urine that is isosmolar with serum. Oliguria, defined as a urine volume of 100 to 400 mL per 24 hours, may be seen with pre-renal (blood flow–dependent), intrinsic (intrarenal), or post-renal (obstructive) causes of acute renal failure (ARF). Alternating oliguria and anuria, although uncommon, is a classic indicator of intermittent obstruction, which occurs as urine collects behind an obstructing stone or tumor and then is allowed to flow past as the obstructing material shifts position.

Urinalysis

The standard urinalysis consists of dipstick screening for heme pigment, protein, glucose, ketones, pH, leukocyte esterase, and nitrite and microscopic examination of a spun specimen of freshly voided urine.

Heme

The dipstick detects both free hemoglobin (or myoglobin) and the hemoglobin contained in red blood cells (RBCs) but is more sensitive to the former. Although as few as 3 RBCs per high-power field can be detected, the dipstick may fail to identify 10 to 15% of patients with microscopic hematuria, as defined by more than 5 RBCs per high-power field. A positive result on dipstick testing should prompt microscopic examination of the urine. If red cells are seen, the diagnosis of hematuria is confirmed. If the dipstick result is positive but findings on microscopic examination are negative, pigmenturia (myoglobin or free hemoglobin) should be suspected.

Protein

The dipstick test for protein, using the color change of tetrabromophenol blue, can detect protein at concentrations of 10 to 15 mg/dL but does not yield reliably positive results until the concentration is greater than 30 mg/dL. Moreover, the relation between color intensity and protein concentration is only approximate. The dipstick reagent is three to five times more sensitive to albumin than to globulins and immunoglobulin light chains (e.g., Bence Jones protein)—an important limitation. False-positive results are caused by alkaline urine, hematuria, or prolonged immersion of the dipstick in the urine. False-negative results are seen with dilute urine.

Microscopic Examination

After dipstick testing of the urine has been completed, 10 mL of urine is placed in a conical test tube and spun at 2000 revolutions per minute for 5 minutes (higher speeds may break up casts). The supernatant is discarded. The sediment is resuspended in the residual urine, and a drop is placed on a slide and covered with a coverslip. Observations are recorded as the number of cells per high-power field. A level of 2 to 3 RBCs per high-power field in adult men or 2 to 4 RBCs per high-power field in adult women commonly is accepted as normal; in many studies, a finding of 5 RBCs per high-power field is considered to represent the threshold of abnormality. Casts are formed from urinary Tamm-Horsfall protein, a product of the tubular epithelial cells that gels at low pH and high concentration and when mixed with albumin, or from red cells, tubular cells, or cellular debris in the urine. The composition of a cast thus reflects the contents of the tubule. Casts are described and classified according to their appearance or constituents (e.g., hyaline, red cell, white cell, granular, or fatty casts) (Fig. 95-1). Hyaline casts, those that are devoid of contents, are seen with dehydration, after exercise, or in association with glomerular proteinuria. Red cell casts indicate glomerular hematuria, as seen in glomerulonephritis; the presence of even a few red cell casts is significant. White cell casts imply the presence of renal parenchymal inflammation. Granular casts are composed of cellular remnants and debris. Fatty casts, like oval fat bodies, generally are associated with heavy proteinuria and nephrotic syndrome.

Microscopic examination of the urinary sediment can be helpful in establishing the cause of ARF. A sediment without
formed elements or with only hyaline casts is characteristic of prerenal azotemia or obstruction. Red cell casts suggest glomerulonephritis or vasculitis. Fatty casts also suggest glomerular disease. In acute tubular necrosis (ATN), the urinary sediment commonly shows granular casts and renal tubular epithelial cells. Large numbers of polymorphonuclear leukocytes are observed in interstitial nephritis, papillary necrosis, and pyelonephritis. Eosinophil-containing casts (appreciated only after staining of the sediment) are typical of allergic interstitial nephritis. Uric acid crystals suggest uric acid nephropathy but are extremely nonspecific; oxalic acid or hippuric acid crystals may be seen in ethylene glycol ingestion.

**Figure 95-1.** Appearance of casts on microscopic examination of the urinary sediment. **A,** Hyaline cast. Brightfield microscopy (250×). **B,** Red cell cast with one polymorphonuclear leukocyte in the matrix (arrow). Brightfield microscopy (250×). **C,** White cell cast. Brightfield microscopy (250×). **D,** Granular cast. Only remnants of cells are present and cell borders are not distinct. The cast is filled with coarse granules from cells that have undergone degeneration. Brightfield microscopy (250×). **E,** Fatty cast. The fat is doubly refractile to polarized light and has a "Maltese cross" pattern. Polarized microscopy (250×). (A-E, Courtesy of the American Society of Clinical Pathologists.)

**Serum and Urine Chemical Analysis**

**Creatinine and Blood Urea Nitrogen**

The normal range for the serum creatinine level extends from 0.5 mg/dL in thin people to 1.5 mg/dL in muscular persons. Spurious elevations can be caused by acetoacetate (which cross-reacts with creatinine in commonly used assays) and by certain medications that either cross-react in the assay or reversibly inhibit tubular creatinine secretion despite a normal GFR. Serum creatinine concentration is a function of the amount of creatinine entering the blood from muscle, its volume of distribution, and its rate of excretion. Because the
first two usually are constant, changes in serum creatinine concentration generally reflect changes in GFR. Under steady-state conditions, if the GFR is halved, the serum creatinine doubles. Abrupt cessation of glomerular filtration causes the serum creatinine to rise by 1 to 2 mg/dL per day. Thus, a daily increment of less than 1 mg/dL suggests that at least some renal function has been preserved. Rhabdomyolysis releases creatine into the plasma and may cause the serum creatinine to increase by more than 2 mg/dL per day.

The blood urea nitrogen (BUN) level also rises with renal dysfunction but is influenced by many extrarenal factors as well. Increased protein intake, gastrointestinal (GI) bleeding, and the catabolic effects of fever, trauma, infection, and drugs such as tetracycline and corticosteroids all increase protein turnover and result in increased hepatic urea production and increased BUN. Conversely, BUN tends to be decreased in patients with liver failure or protein malnutrition.

When glomerular filtrate has been formed, renal urea clearance is largely a function of flow rate. Urea clearance is thus decreased in patients with prerenal azotemia or acute obstruction, despite preservation of tubular function. In such cases, the BUN/creatinine ratio usually is greater than the normal value of 10:1, whereas this ratio usually is not markedly increased in cases of uncomplicated intrinsic ARF.

**Urine Sodium and Fractional Excretion of Sodium**

Measurement of the urine sodium concentration provides information on the integrity of tubular reabsorptive function. Normally, urine sodium concentration parallels sodium intake. Low urine sodium concentration thus indicates not only intact reabsorptive function but also the presence of a stimulus to conserve sodium. The urine sodium concentration, as well as the fractional excretion of sodium (FENa), an additional measure of tubular sodium handling, helps distinguish between the two most common causes of ARF: prerenal azotemia and ATN (Table 95-1).

Urinary indices are most helpful in oliguric patients. In general, an oliguric patient with a urine sodium concentration less than 20 mEq/L and FENa less than 1% should be considered to have prerenal azotemia, whereas urine sodium concentration greater than 40 mEq/L and FENa greater than 1% suggest ATN. Values in patients with prerenal azotemia overlap somewhat with those in patients with nonoliguric ATN, particularly if the renal injury is mild and some capability to retain sodium has been preserved. Thus, intermediate values for urine sodium concentration and FENa are of little help in differentiating between the two conditions. The administration of mannitol or a loop diuretic within the several hours preceding urine collection also may make interpretation of urine values difficult because the urinary sodium will tend to be higher and the urine less concentrated, causing the results in prerenal azotemia to resemble those in intrinsic renal failure (Box 95-1).

In glomerulonephritis, the urinary indices generally reflect intact tubular sodium handling, but the diagnosis is more accurately made by urine microscopy. In obstructive uropathy, the values of the urinary indices depend on the duration of obstruction and cannot be relied on to indicate either the presence or absence of obstruction.

### Renal Imaging

#### General Considerations

Renal imaging often is helpful in evaluating the patient with kidney dysfunction, particularly when obstruction is suspected. Contrast-enhanced computed tomography (CT) scanning provides an anatomic image of the urinary tract but does not provide an evaluation of renal function. The classic findings of obstruction are kidneys that are normal to large in size, nephrograms that become increasingly dense, and delayed opacification of dilated collecting systems. However, contrast-enhanced CT subjects the kidneys of an already azotemic patient to the risk of an additional potential insult from the contrast agent (Fig. 95-2). Although the newer nonionic isosmolar contrast agents may have less potential for nephrotoxicity, techniques such as ultrasonography and CT scanning that do not involve contrast administration are much preferred in patients with preexisting renal insufficiency.

#### Computed Tomography

Noncontrast CT scanning may be useful in evaluating some azotemic patients. Hydronephrosis can be recognized without the use of contrast material. Often, dilated ureters also can be seen without contrast enhancement and the level of obstruction determined. Moreover, the cause of obstruction (e.g., lymphoma, retroperitoneal hemorrhage, metastatic cancer, retroperitoneal fibrosis) often can be delineated as well. Occasionally, obstruction severe enough to result in renal failure may not cause detectable proximal dilatation of the urinary tract. Bilateral ureteral obstruction produced by

malignancy or retroperitoneal fibrosis is the most important cause of this nondilated obstructive uropathy. When noninvasive studies yield negative results, the diagnosis must be made by retrograde pyelography or by antegrade pyelography performed through a percutaneous nephrostomy.

Ultrasonography

Ultrasonography allows accurate measurement of renal dimensions and is a safe and reasonably reliable method of excluding obstruction as a cause of ARF. The normal kidney shows an echo-free renal parenchyma surrounding the echogenic central urothelium of the renal pelvis and calices. The sonographic appearance of the kidney in obstruction is that of an enlarged central sonolucent area that spreads the normal central echo densities. A similar pattern may be produced by renal cysts, but without associated ureteral dilatation. Dilatation of the collecting system generally is apparent within 24 to 36 hours of the onset of obstruction, but obstruction may be overlooked in patients who are evaluated early in the development of obstructive ARF.

HEMATURIA AND PROTEINURIA

Hematuria

Principles of Disease. Microscopic hematuria often is discovered incidentally on routine urinalysis, but as little as 1 mL of blood in 1 L of urine can cause grossly appreciable hematuria. Although not invariably a sign of disease, the finding of hematuria calls for an effort to rule out any treatable underlying disorder. Both gross and microscopic hematuria are caused by similar disorders, but the amount of blood in the urine does not correlate with the severity or the seriousness of the etiologic condition.2,3

The causes of hematuria can be divided into hematologic, renal, and postrenal causes; renal causes may be further classified as glomerular or nonglomerular (Box 95-2). Overall, the most common causes of nontraumatic hematuria, in roughly descending order of occurrence, are kidney stones, carcinoma of the kidney or bladder, urethritis, urinary tract infection (UTI), benign prostatic hypertrophy, and glomerulonephritis. The scope of the differential diagnosis can be narrowed by taking into account the patient’s age and sex (Table 95-2) and by distinguishing between upper and lower urinary tract sources. When gross hematuria is present, cystoscopy can determine whether blood is emerging from one or both ureteral orifices, thereby defining a source in the upper tract. Red cell casts indicate a renal source, as does associated proteinuria (excretion of greater than 500 mg of albumin in 24 hours). In differentiating between proteinuria due to renal parenchymal disease and that simply produced by admixture of urine with extravasated blood, a useful rule of thumb is that 1 mL of whole blood contains approximately 5 billion RBCs and approximately 50 mg of albumin.

ED evaluation of the patient with gross or microscopic hematuria should begin with a complete history to define the

BOX 95-2

CAUSES OF HEMATURIA

Hematologic
- Coagulopathy
- Sickle hemoglobinopathies

Renal
- Glomerular
  - Primary glomerular disease
  - Multisystem disease (e.g., systemic lupus erythematosus, Henoch-Schönlein purpura, hemolytic uremic syndrome, polycystic kidney disease)

Nonglomerular
- Renal infarction
- Tuberculosis
- Pyelonephritis
- Polycystic kidney disease
- Medullary sponge kidney
- Acute interstitial nephritis
- Tumor
- Vascular malformation
- Trauma
- Papillary necrosis

Postrenal
- Stones
- Tumor of ureter, bladder, urethra
- Cystitis
- Tuberculosis
- Prostatitis, urethritis
- Foley catheter placement
- Exercise
- Benign prostatic hypertrophy
significant underlying disease can be identified in at least 70% of cases. When hematuria is associated with anticoagulant use, an investigation of the possible underlying cause is indicated. Even if white cells or organisms are not identified, a finding of proteinuria should be confirmed and the amount of protein measured. A positive dipstick test result for protein, but gross hematuria that resolves spontaneously within a few days, usually indicates a nonglomerular renal or lower urinary tract source of bleeding. Hematuria may rarely be cyclic or associated with menses, suggesting endometriosis of the ureter or bladder. Flank pain suggests calculus, neoplasm, renal infarction, obstruction, or infection as the cause. Symptoms of frequency, dysuria, and suprapubic pain suggest cystitis or urethritis; in adult men, perineal pain, dysuria, and terminal hematuria suggest prostatitis.

Other clues to the cause should be sought by careful questioning. Because glomerulonephritis or interstitial nephritis may be caused by a variety of bacterial, viral, and parasitic infections, a history of recent infection is important. Symptoms suggestive of a multisystem disorder (e.g., systemic lupus erythematosus) also should be sought, as should a history of human immunodeficiency virus infection. Because drugs may cause acute interstitial nephritis (AIN), papillary necrosis, or hemorrhagic cystitis, a complete medication history should be elicited. When hematuria is associated with anticoagulant use, significant underlying disease can be identified in at least 70% of patients. The family history should be elicited because it may provide a clue to the presence of polycystic or other familial kidney disease, sickle cell disease, or renal calculi. A history of recent strenuous exercise is important to identify; 15 to 20% of normal persons exhibit hematuria after strenuous exercise. The mechanism is unclear, but the hematuria resolves spontaneously within a few days.

**Clinical Features.** On physical examination, findings of arthritis, skin lesions, hypertension, or edema suggest underlying glomerulonephritis. Examination of the external genitalia may reveal a urethral meatal lesion that may be the source of bleeding; in adult women, a pelvic examination should be performed to exclude vulvovaginal sources of blood. Because endocarditis or atrial fibrillation may cause renal embolism, the patient should be checked for a new heart murmur or an irregular rhythm. Costovertebral angle tenderness suggests pyelonephritis or stone disease, and a palpably enlarged kidney suggests polycystic kidney disease or renal malignancy. The prostatic examination may offer clues to the presence of prostatitis, benign prostatic hypertrophy, or cancer.

**Laboratory Findings.** Evaluation of hematuria in the ED setting should include assessment of the blood pressure and measurement of the BUN and serum creatinine levels to gauge the patient’s underlying renal function, but urinalysis can be expected to provide more specific information. Red urine that is dipstick-negative and free of red cells on microscopy may be caused by ingestion of beets, red berries, or food coloring; by urate crystals; or by drugs such as phenazopyridine (Pyridium) and rifampin. A finding of red cell or other casts or lipiduria or significant proteinuria in combination with hematuria suggests intrinsic renal disease, and appropriate referral should be made. Microscopic hematuria usually does not produce a positive dipstick test result for protein, but gross hematuria may contribute enough protein to cause a positive result; thus, a finding of proteinuria should be confirmed and the amount quantitated in a 24-hour urine collection. Hematuria in combination with pyuria or bacteriuria suggests UTI; the infection should be treated and hematuria reassessed after therapy has been completed. Even if white cells or organisms are not seen on urinalysis, the urine should be cultured to rule out hemorrhagic cystitis, especially when lower tract symptoms are present.

Blood studies should be ordered only as necessary to gauge renal function and to confirm causes suggested by the clinical presentation. In the ED setting, routine ordering of the full gamut of chemical and serologic studies necessary to rule out all possible causes of hematuria is rarely appropriate. In particular, a platelet count and coagulation studies are extremely unlikely to be helpful in the absence of a suggestive history or other specific clinical clues.

Radiography and Ultrasonography. The role of urinary tract imaging studies in the immediate evaluation of hematuria also is limited. Visualization of the urinary tract generally is helpful only when the history suggests renal colic or other disorders of the upper urinary tract (e.g., polycystic kidney disease, tumor, obstruction). CT scanning without contrast has emerged as the imaging modality of choice. Ultrasonography can be used to determine kidney size and shape and to detect renal masses or obstruction. Further imaging studies, if indicated, should be planned after urologic consultation.

If no upper tract lesions are identified on initial imaging studies, cystoscopy usually is the next step in evaluation because it is the most effective means of visualizing the bladder and the male urethra. It is the initial study of choice for patients with active gross hematuria; in fact, some urologists prefer to perform endoscopic procedures promptly during an acute bleeding episode to maximize the chance of localizing the source. In older patients in whom urinalysis shows only hematuria and the findings on the history and physical examination are otherwise unhelpful, urinary cytologic examination also may be undertaken.

Monitoring on an outpatient basis constitutes appropriate management in patients with hematuria who have no other abnormality revealed by urinalysis, who are otherwise asymptomatic, who are not azotemic, hypertensive, or severely anemic, and who have no evidence of intrinsic renal disease. (A possible exception may be the patient with a known bleeding disorder.) Extensive outpatient evaluation for an isolated episode of hematuria usually is not undertaken in patients younger than 40 years of age unless hematuria is persistent, but most patients older than 40 years should undergo a thorough evaluation after even a single episode of hematuria.

The cause of hematuria can be determined on initial medical and urologic evaluation in 70 to 80% of cases. In other cases, a diagnosis of small calculi, occult bladder tumor, arteriovenous malformation, or early glomerulonephritis is made only after repeated examination or the development of further signs or symptoms. In 5 to 10% of cases, no cause can be determined.

**Proteinuria**

**Principles of Disease.** Abnormal proteinuria is defined as excretion of more than 150 mg of protein (albumin) per 24 hours in adults, or more than 140 mg/m² per 24 hours in children. Patients with mild to moderate degrees of proteinuria commonly are identified incidentally on routine urinalysis; patients with more severe degrees of proteinuria often seek medical attention because of edema or other effects of hypoproteinemia.

With alteration in the glomerular capillary barrier (e.g., with the nephrotic syndrome and the many varieties of primary and secondary glomerulonephritis), albumin and globulins, which under normal circumstances are restricted from the glomerular ultrafiltrate because of their ionic charge and size, are lost into the urine. Persistent proteinuria is a marker for renal disease even in the absence of azotemia or an abnormal urine sediment.
PART III ■ Medicine and Surgery / Section Six • Genitourinary and Gynecologic Systems

1262

Excretion of more than 2 g of protein in 24 hours is likely
to be caused by a glomerular process. In the nephrotic syndrome,
protein losses exceed the liver’s capacity to synthesize albumin,
resulting in hypoalbuminemia. This leads to decreased plasma
oncotic pressure and accumulation of edema fluid in the extravascular interstitial space. Increased aldosterone secretion and
further retention of salt and water ensue. Thus, edema is the
clinical hallmark of the nephrotic syndrome and often is the
initial complaint of patients who have significant proteinuria.
Edema ranges in severity from mild dependent peripheral
edema or periorbital swelling to frank anasarca with pleural
effusions and ascites. Nephrotic-range proteinuria is defined
arbitrarily as excretion of greater than 3.5 g of protein per
24 hours.
Patients with the nephrotic syndrome are at increased risk
for thromboembolic events, including deep vein thrombosis of
the lower extremity, renal vein thrombosis, and pulmonary
embolism. The reason for this propensity appears to be a
hypercoagulable state that may be related in part to urinary
loss and decreased plasma levels of antithrombin III, proteins,
and fibrinolytic factors.1 Hyperlipidemia is another typical
feature of the nephrotic syndrome; the mechanism is thought
to be related indirectly to hypoalbuminemia and decreased
oncotic pressure or viscosity. The major clinical significance of
the nephrotic syndrome, however, is that it indicates the presence of an underlying renal process or systemic disease affecting the glomerulus (Box 95-3).
Clinical Features. Evaluation of the patient with proteinuria
focuses not only on gauging the severity of proteinuria and the
likelihood of complications but also on identifying any associated signs of underlying renal disease or systemic illness.
Careful questioning will elicit a history of recent infections or
use of medications or drugs or a past history of proteinuria,
hypertension, edema, or renal disease. In young female
patients, the possibility of pregnancy should be kept in mind
because pregnancy can exacerbate previously inapparent renal
disease; in late pregnancy, proteinuria may be the first sign of
preeclampsia. Clues to the presence of systemic diseases that
commonly affect the kidneys (e.g., diabetes, collagen vascular
disease) should be sought as well. The physical examination
should include evaluation of the blood pressure, determination
of the presence or absence of edema, and assessment for signs
of systemic disease or renal insufficiency.
Laboratory Findings. The laboratory evaluation in the patient
with proteinuria should include urinalysis and measurement
of the BUN and serum creatinine. Although the finding of
isolated proteinuria may or may not be clinically important,
proteinuria is almost always significant when it occurs in combination with hematuria. RBCs and red cell casts suggest glomerulonephritis; proteinuria with pyuria may be seen with
AIN. The combination of proteinuria and glycosuria suggests
diabetic nephropathy. A 24-hour urine collection should be
ordered to provide an accurate measure of GFR and to quantitate protein excretion.
Abnormal findings on the history, physical examination, or
laboratory evaluation greatly increase the probability of the
presence of significant renal disease, and early referral to an
internist or nephrologist is indicated. However, in the absence
of edema, azotemia, hypertension, active urine sediment, or
known systemic illness affecting the kidney, patients with
proteinuria may be referred to their primary care provider for
follow-up. Because transient, mild proteinuria is not uncommon in healthy persons, patients with mild proteinuria as
indicated by dipstick testing (particularly if the urine is
concentrated) should have dipstick testing repeated at followup visit before further evaluation is undertaken. Persistent
proteinuria may require referral to a nephrologist; in some

■ ACUTE RENAL FAILURE
The hallmark of ARF is progressive azotemia, which commonly is accompanied by a wide range of other disturbances,
depending on the severity and duration of renal dysfunction.
These include metabolic derangements (e.g., metabolic acidosis and hyperkalemia), disturbances of body fluid balance
(particularly volume overload), and a variety of effects on
almost every organ system (Box 95-4).
The causes of ARF may be divided into those that decrease
renal blood flow (prerenal), produce a renal parenchymal insult
(intrarenal), or obstruct urine flow (obstructive or postrenal).
Identification of either a prerenal or a postrenal cause of ARF
generally makes it possible to initiate specific corrective
therapy; if these two broad categories of ARF can be excluded,
an intrarenal cause is implicated. The renal parenchymal
causes of ARF can be usefully subdivided into those primarily


affecting the glomeruli, the intrarenal vasculature, or the renal interstitium. The term *acute tubular necrosis* denotes another broad category of intrinsic renal failure that cannot be attributed to specific glomerular, vascular, or interstitial causes (Fig. 95-3).

**Principles of Disease**

**Prerenal Azotemia**

Decreased renal perfusion that is sufficient to cause a decrease in the GFR results in azotemia. The possible causes can be grouped into entities causing intravascular volume depletion, volume redistribution, or decreased cardiac output (Box 95-5). Patients who have preexisting renal disease are particularly sensitive to the effects of diminished renal perfusion.

Prerenal azotemia is characterized by increased urine specific gravity, BUN/creatinine ratio greater than 10:1, urine sodium concentration less than 20 mEq/dL, and FENa less than 1%. The condition generally can be corrected readily by expanding extracellular fluid volume, augmenting cardiac output, or discontinuing vasodilating antihypertensive drugs. However, severe prolonged prerenal azotemia can eventuate in ATN.
Patients who have congestive heart failure (CHF) or cirrhosis form an important subset of those with prerenal azotemia. These patients often are salt-overloaded and water-overloaded, yet their effective intra-arterial volume is decreased. Administration of diuretics has the potential to decrease intravascular volume further, resulting in decreased glomerular filtration and prerenal azotemia. For some patients with advanced CHF or hepatic disease, a state of chronic stable prerenal azotemia may be the best achievable compromise between symptomatic volume overload and severe renal hypoperoxidation.

Glomerular perfusion also may be decreased in patients with normal intravascular volume and normal renal blood flow who take angiotensin-converting enzyme (ACE) inhibitors or, more commonly, prostaglandin inhibitors. All nonsteroidal anti-inflammatory drugs (NSAIDs), including aspirin, inhibit prostaglandin synthesis. Renal vasodilator prostaglandins are critical in maintaining glomerular perfusion in patients with conditions such as CHF, chronic renal insufficiency, and cirrhosis, in which elevated circulating levels of renin and angiotensin II act to diminish renal blood flow and GFR. In this setting, decreased production of vasodilator prostaglandins may result in acute intrarenal hemodynamic changes and a reversible decrease in renal function. This phenomenon also is seen with the newer, selective cyclooxygenase-2 inhibitor class of NSAIDs. Other risk factors include advanced age, diuretic use, renovascular disease, and diabetes. This entity is distinct from other renal complications of NSAIDs, including interstitial nephritis and papillary necrosis.

Renal insufficiency secondary to NSAIDs generally is reversible after withdrawal of the causative agent. For patients who are at increased risk but require treatment with NSAIDs, a short-acting preparation (e.g., ibuprofen) should be prescribed, and follow-up monitoring of renal function and serum potassium level should begin within days rather than weeks. If renal function is unchanged after a short course of treatment, adverse effects from continuing therapy are unlikely, although other potential mechanisms for the development of renal dysfunction (e.g., interstitial nephritis) should be kept in mind.

Postrenal (Obstructive) Acute Renal Failure

Obstruction is an eminently reversible cause of ARF and should be considered in every patient with newly discovered azotemia or worsening renal function. Obstruction may occur at any level of the urinary tract but most commonly is produced by prostatic hypertrophy or by functional bladder neck obstruction (e.g., secondary to medication side effects or neurogenic bladder) (Box 95-6). Intrarenal obstruction may result from intratubular precipitation of uric acid crystals (e.g., with tumor lysis), oxalic acid (as in ethylene glycol ingestion), myeloma proteins, methotrexate, sulfadiazine, acyclovir, or indinavir. Bilateral ureteral obstruction (or obstruction of the ureter of a solitary kidney) may be caused by retroperitoneal fibrosis, tumor, surgical misadventure, stones, or blood clots. A sudden deterioration in renal function in the setting of diabetes mellitus, analgesic nephropathy, or sickle cell disease should suggest papillary necrosis.

Treatment of postrenal ARF consists of relief of the obstruction. In the absence of infection, full renal recovery is possible even after 1 to 2 weeks of total obstruction, although the serum creatinine level may not return to baseline for several weeks. Because the onset of irreversible loss of renal function with obstruction appears to be gradual, a few days’ delay in diagnosis generally is considered acceptable. Still, common sense dictates that obstructions should be detected and relieved promptly.

**Intrinsic Acute Renal Failure**

Of the specific intrarenal disorders that cause ARF, glomerulonephritis, interstitial nephritis, and abnormalities of the intrarenal vasculature are amenable to specific therapy and thus should be carefully considered as possible causes. These entities are responsible for only 5 to 10% of cases of ARF in adult inpatients; most are due to ATN. In adults in whom ARF develops outside the hospital, the incidence of glomerular, interstitial, and small-vessel disease is much greater. In children, these entities account for approximately one half of the cases of ARF (Box 95-7).

**Glomerular Disease**

Acute glomerulonephritis may represent a primary renal process or may be the manifestation of any of a wide range of other disease entities (see Box 95-7). Patients may have dark urine, hypertension, edema, or CHF (secondary to volume overload) or may be completely asymptomatic, in which case the diagnosis rests on an incidental finding on urinalysis. The hematuria associated with glomerular disease may be microscopic or gross and may be persistent or intermittent. Proteinuria, although often in the range of 500 mg/day to 3 g/day, is not uncommonly in the nephrotic range. Presence of hematuria, proteinuria, or red cell casts is highly suggestive of glomerulonephritis. In fact, red cell casts are essentially diagnostic of active glomerular disease, although occasionally they are seen with other types of renal disease. Conversely, the absence of red cell casts, proteinuria, and hematuria essentially excludes glomerulonephritis as the cause of ARF.

The specific diagnosis of acute glomerulonephritis caused by primary renal disease often is ultimately made by renal biopsy. However, when glomerulonephritis is secondary to a systemic disease such as systemic lupus erythematosus, the patient’s clinical signs and symptoms, in combination with the results of laboratory assessment, aid considerably in narrowing the scope of the differential diagnosis. As a rule, extensive laboratory testing to identify the cause of acute glomerulonephritis is not indicated in the ED setting and is more appropriately performed as part of an inpatient evaluation.

**Interstitial Disease**

absence of a clear relationship to the dose and the recurrence of the syndrome on rechallenge with the offending agent suggests that an immunologic mechanism is responsible. the most commonly incriminated drugs are the penicillins, diuretics, anticoagulants, and nsaid’s. ain has been reported in association with bacterial, fungal, protozoan, and rickettsial infections.

patients with ain classically have rash, fever, eosinophilia, and eosinophiluria, but it is common for one or more of these cardinal signs to be absent. pyuria, gross or microscopic hematuria, and mild proteinuria are observed in some cases. a definite diagnosis sometimes can be made only on renal biopsy.

Treatment of ain is directed at removing the presumed cause; infections should be treated and offending drugs discontinued. renal function generally returns to baseline over several weeks, although chronic renal failure has been reported to occur.

intrarenal vascular disease

vascular disease of the kidney can be classified according to the size of the vessel that is affected. disorders such as renal arterial thrombosis or embolism, which affect large blood vessels, must be bilateral (or must affect a single functioning kidney) to produce arf. whether to attribute such cases of arf to prerenal or intrarenal vascular causes is a matter of semantics. the most common cause of thrombosis probably is trauma; thrombosis also may occur after angiography or may be secondary to aortic or renal arterial dissection. renal atheroembolism is thought to occur commonly—at least on a microscopic level—after arteriography but is an uncommon cause of arf. similarly, patients with chronic atrial fibrillation or infective endocarditis may experience embolization of the kidney but rarely suffer arf as a result. renal arterial embolism can cause acute renal infarction, generally manifested by sudden flank, back, chest, or upper abdominal pain. urinary findings, including hematuria, are variable. fever, nausea, and vomiting are not uncommon; in some cases, evidence of embolization to other vessels provides a useful clue. the diagnosis usually is made by renal flow scanning or arteriography. surgical embolectomy has been reported to restore function when undertaken within several hours of occlusion, but significant return of function has been documented in patients operated on as long as 6 weeks after total occlusion. this outcome presumably is possible because collateral circulation has developed in association with a preexisting partial occlusion.

an interesting but relatively uncommon type of arf occurs when an ace inhibitor is given to a patient with underlying bilateral renal artery stenosis (or unilateral stenosis of a solitary functioning kidney). with inhibition of angiotensin synthesis, efferent arteriolar tone is not maintained and gfr decreases. the condition is reversible with cessation of therapy.

several diseases that affect the smaller intrarenal vessels can cause arf (see box 95-7). patients whose disease is severe enough to cause arf also generally are found to have hypertension, microangiopathic hemolytic anemia, and other systemic and organ-specific manifestations. infection with escherichia coli O157:H7 has emerged as a major cause of hemolytic uremic syndrome, an important cause of arf in children.

Malignant hypertension, although much less common since the advent of more effective antihypertensive therapy, has by no means disappeared. patients with scleroderma (systemic sclerosis) may have “scleroderma renal crisis,” characterized by malignant hypertension and rapidly progressive renal failure. whereas vasculitis associated with glomerular capillary inflammation typically causes gross or microscopic hematuria and formation of red cell casts, vascular involvement of the medium-size vessels, such as that produced by scleroderma, often spares the preglomerular vessels and tends not to produce an active urine sediment. extrarenal manifestations (rash, fever, arthritis, pulmonary symptoms) are usually evident.

For malignant hypertension both as a separate entity and as a part of scleroderma renal crisis, appropriate treatment can produce a gratifying remission of arf. patients with malignant hypertension have been reported to recover renal function after aggressive antihypertensive therapy, with temporary maintenance with dialysis if necessary. in patients with scleroderma renal crisis, specific therapy with ace inhibitors...
Acute Tubular Necrosis

The term *acute tubular necrosis* refers to a generally reversible deterioration of kidney function associated with a variety of renal insults. Oliguria may or may not be a feature. The diagnosis is made after prerenal and postrenal causes of ARF and disorders of glomeruli, interstitium, and intrarenal vasculature have been excluded. These discrete categories do overlap in a few disorders. For example, ARF associated with multiple myeloma or ethylene glycol toxicity is associated with both intrarenal obstruction and interstitial disease, as well as probably having a direct toxic effect on the renal tubule itself.

The most common precipitant of ATN is renal ischemia occurring during surgery or after trauma and sepsis. The remainder of cases occur in the setting of medical illness, most commonly as a result of the administration of nephrotoxic aminoglycoside antibiotics or radiocontrast agents or in association with rhabdomyolysis. Multiple causes can be identified in some cases; in others, a definitive cause is never established.

Decreased renal perfusion results in a continuum of renal dysfunction that ranges from transient prerenal azotemia at one extreme to ATN at the other. Early during the period of renal ischemia, renal function can be restored completely by restoring renal blood flow, but at some point, continued hypoperfusion will result in renal dysfunction unresponsive to volume repletion and ATN will supervene. ATN may occur in the absence of frank hypotension; even modest renal ischemia may result in ATN in susceptible persons. Individual susceptibility to ATN may be related to the balance of prostaglandin-mediated vasopressor and vasodilatory influences on the renal vasculature.

Postischemic ATN can occur in the setting of volume loss from the GI tract (upper or lower), skin, or kidneys or can result from severe hemorrhage or major burns. Heatstroke commonly is associated with the development of ATN, which is thought to result from a combination of volume loss, hyperpyrexia, and rhabdomyolysis. Another cause of ATN is hyperglycemic hyperosmolar nonketotic coma, which can be associated with loss of as much as 25% of total body water. ATN also is seen in the setting of cardiogenic shock, sepsis, and third spacing of fluids in pancreatitis and peritonitis.

ATN is common in postoperative patients, although not all cases can be attributed to intraoperative hypotension or hemorrhage. Concomitant sepsis, increased age, preexisting renal disease, and other comorbid conditions are associated with a worse outcome.

Nephrotoxins constitute the other major cause of ATN. Among the most prominent of these are the endogenous pigments myoglobin and hemoglobin. Rhabdomyolysis and ARF resulting from crush injuries first received widespread attention after their description in survivors of the London blitz during World War II, but many other causes of pigment nephropathy have been reported (Box 95-8). Hypotension secondary to fluid loss into damaged muscle is thought to worsen the effects of myoglobinuria on the renal tubule, as does acidosis. Hemolysis, resulting in the release of hemoglobin into the circulation and hemoglobinuria, can cause ATN but usually only in the presence of coexisting dehydration, acidosis, or other causes of decreased renal perfusion. ATN may be produced by the hemolysis of as little as 100 mL of blood.

ATN associated with rhabdomyolysis is often oliguric; it is characterized by rapid increases in the serum creatinine, potassium, phosphorus, and uric acid levels. Creatine released from muscle is metabolized to creatinine, which may result in serum creatinine increases of more than 2 mg/dL per day, in contrast with the increase of 0.5 to 1.0 mg/dL per day typically seen in other forms of ARF. The BUN/creatinine ratio often is less than 10:1. Intracellular potassium released from damaged muscle may raise the serum potassium by 1 to 2 mEq/L in several hours. Likewise, phosphate released from muscle may cause dramatic increases in the serum phosphate level. Uric acid, produced by metabolism of purines released from damaged muscle, may accumulate to levels high enough to suggest acute uric acid nephropathy.

Urine dipstick testing yields a positive result for heme in only 50% of patients with rhabdomyolysis, because myoglobin is rapidly cleared from the serum and may therefore be undetectable in the urine at the time of presentation. Thus, a negative result on urine dipstick testing does not rule out the diagnosis. Serum creatine kinase (CK) is cleared much more slowly, so measurement of serum CK levels is a much more sensitive test.

No biochemical parameter can be used to predict which patients who have rhabdomyolysis will experience ARF. In one classic study of patients in whom alcoholism, muscle compression, and seizures were the most common causes of rhabdomyolysis, ARF developed in only one third. Neither the degree of serum CK elevation, the presence (or absence) of myoglobinuria, nor the degree of hyperkalemia correlated well with the development of ARF.

Antibiotics and radiographic contrast agents are other nephrotoxins that commonly are implicated in the development of ATN. Aminoglycosides are the most commonly implicated antibiotics. Higher doses and longer duration of therapy are associated with higher serum drug levels, leading to greater accumulation of drug in the renal parenchyma and a greater likelihood of nephrotoxicity. Increased age, impaired renal function, dehydration, and exposure to other nephrotoxins are additional risk factors. Once-daily administration of a somewhat higher dose is associated with less nephrotoxicity but equal effectiveness.

Aminoglycoside-induced ATN typically has a gradual onset. Clinically significant renal dysfunction usually occurs only after several days and often after more than a week of therapy. However, renal failure can develop as late as 10 days after a

drug has been discontinued, an observation that appears to be explained by the prolonged tissue half-life characteristic of these agents. Renal function returns to normal after an average of 6 weeks, but the condition occasionally progresses to permanent renal injury.

Radiographic contrast agents constitute a common cause of hospital-acquired renal insufficiency. Renal failure produced by these agents may be defined as an increase in serum creatinine level of 25% over baseline with a temporal relation to contrast medium administration and in the absence of other identifiable causes. Radiocontrast agent–induced ATN encompasses a spectrum ranging from asymptomatic nonoliguric renal insufficiency to severe renal failure requiring dialysis, but most cases are mild. It can occur after any procedure involving intravascular administration of contrast material. Typically, an increase in the serum creatinine level is noted within 3 days of exposure, with a return to normal within 10 to 14 days.

The most important risk factors for radiocontrast agent–induced ATN are preexisting renal insufficiency, diabetes mellitus, multiple myeloma, age older than 60 years, volume depletion, and higher doses of contrast material. Among these, preexisting renal insufficiency is the most important. Diabetic patients with a serum creatinine level less than 1.5 mg/dL are at low risk for the development of radiocontrast agent–induced ATN, whereas those whose serum creatinine is greater than 1.5 mg/dL are at significant risk. Multiple myeloma, particularly in patients who are dehydrated, is another reasonably well-documented risk factor. Advanced age also appears to make ATN more likely, possibly because of decreased renal mass and cortical blood flow. Volume depletion appears to be an independent risk factor, and aggressive volume expansion before contrast exposure has been shown to have a protective effect. Finally, large doses and repeated doses of contrast material are associated with increased risk of ATN, particularly if a second study is performed within 72 hours of the first. Use of low-osmolality contrast media appears to be associated with a lower risk of nephrotoxicity than that with use of standard high-osmolality agents.

Oral N-acetylcysteine has been shown to have some protective effect when given prophylactically for 2 days before coronary angiography, and in some studies when given much closer to the time of contrast exposure. However, other analyses cast doubt on the feasibility and effectiveness of N-acetylcysteine in the ED setting. A rapid-treatment regimen of modest volumes of intravenous NaHCO₃ (3 mL/kg over 1 hour, followed by 1 mL/kg per hour for 6 hours after contrast exposure) appears to be effective in decreasing the likelihood of nephrotoxicity and is more appropriate for use in the ED.

Clinical Features

When the presence of azotemia or renal failure has been discovered, the first consideration in the ED evaluation should be the possibility of potentially life-threatening complications (e.g., hyperkalemia, pulmonary edema). Assuming these have been satisfactorily ruled out, the next step is to determine whether the condition represents ARF or is the result of preexisting renal disease. The clinical distinction between ARF and chronic renal failure often is difficult; old records and laboratory results are invaluable. The finding of small kidneys on abdominal radiography or bone changes of secondary hyperparathyroidism on hand films suggests that the renal failure is chronic. Anemia, hypocalemia, and hyperphosphatemia, on the other hand, should not be relied on to identify patients who have chronic renal failure because these abnormalities can develop rapidly in ARF.

In evaluating the patient with azotemia, the history, physical examination, and laboratory studies should seek clues to the cause and identify signs and symptoms of uremia, volume overload, or other complications of renal failure. In attempting to identify the cause of azotemia, the general strategy is to rule out both prerenal and postrenal causes before considering the many intrinsic renal causes. First, potential sources of volume loss and causes of decreased cardiac output should be sought in the history, and the patient should be questioned about lightheadedness, bleeding, GI fluid loss, abnormal polyuria, or symptoms of CHF. In men, a history of nocturia, frequency, hesitancy, or decreased urinary stream suggests prostatic obstruction. A history of lower tract symptoms or of abdominal or pelvic tumor in either sex should likewise be elicited, as should a history of kidney stones or chronic UTI. As documented in the history, acute anuria (defined as the production of urine at less than 100 mL/day) most often is the result of high-grade urinary tract obstruction, although it also may accompany severe volume depletion, severe acute glomerulonephritis, cortical necrosis, or bilateral renal vascular occlusion. Intermittent anuria, on the other hand, is characteristic of obstructive disease.

The patient should be questioned about medication use and possible exposure to radiographic contrast agents or other exogenous toxins. A history of hypertension, dark-colored urine, rash, fever, or arthritis suggests intrinsic renal disease or a multisystem disorder. In older patients, presence of symptoms suggestive of multiple myeloma should be elicited.

The physical examination should focus on signs of volume depletion such as orthostatic hypotension, tachycardia, and decreased skin turgor. Documented short-term changes in body weight offer a valuable clue in assessing volume status, particularly in chronically ill patients. In addition, suspected bleeding should be specifically excluded. Similarly, volume overload should be sought by assessment of jugular vein distention and attention to the presence of rales, an S₃ gallop, or edema.

An attempt to percuss the bladder should be made. A distended bladder is percussible when it contains 150 mL of urine, and the dome is palpable abdominally when it contains 500 mL. Ultrasonography can be used to detect bladder distention or postvoid residual volume if there is a question of urethral retention.

Prostate examination in adult men and pelvic examination in adult women should not be neglected. Rash, purpura, pallor, or petechiae should be noted, as should arthritis, musculoskeletal tenderness, or findings suggestive of infection or malignancy.

Diagnostic Strategy

Laboratory Findings. The laboratory evaluation should begin with a dipstick and microscopic urinalysis and measurement of urine output. BUN, serum creatinine, urine sodium, and FENa levels should be determined to help evaluate renal function and to provide clues to the cause of ARF. A complete blood count, serum electrolyte panel (expanded to include calcium, phosphorus, and magnesium determinations), electrocardiogram (ECG), and chest radiograph should be ordered to establish the patient's baseline status and to provide information about possible complications. Other studies may be of value in the ED setting when the history or physical findings suggest that they may have a specific role in immediate diagnosis or management.

Prerenal azotemia should be suspected in the setting of volume loss, volume redistribution, or decreased effective renal perfusion. It typically is associated with a normal urinoly-
sis, high BUN/creatinine ratio, increased urine osmolality, urine sodium concentration less than 20 mEq/L, and FENA less than 1%. A rapid response to volume repletion also is characteristic.

Urethral or bladder neck obstruction is documented by the finding of significant amounts of residual urine in the bladder (by catheterization or ultrasound examination) after the patient has voided or attempted to void spontaneously. An important point is that the ability to void does not rule out obstruction. In fact, the urine volume in the presence of obstruction may range from zero to several liters per day. Flank pain is likewise an insensitive marker for obstruction. Urine indices and the BUN/creatinine ratio tend not to be helpful, although an increase in the latter is common in obstruction. A renal parenchymal disorder often can be diagnosed by its manifestations on microscopic urinalysis or by associated extrarenal manifestations (e.g., with multisystem disease) or the clinical setting (e.g., recent exposure to a new medication). The absence of evidence for prerenal or postrenal causes in a patient with ARF may be taken as presumptive evidence of an intrarenal parenchymal process. Among these, the possibility of an acute or ongoing vascular insult should be kept in mind, because timely intervention may be important in preserving ultimate renal function.

Radiography and Ultrasonography. Significant hydronephrosis usually is readily demonstrable by ultrasonography and may indicate either upper or lower tract obstruction. In questionable cases, or if bilateral ureteral obstruction is strongly suspected on the basis of clinical findings, the next step is retrograde urography performed by a urologist. CT imaging is less useful in this setting; in fact, intravenous radiocontrast material may compound the injury to the kidney.

Management

ED management of ARF is directed at reversing decreases in GFR and urine output (if possible) while minimizing further hemodynamic and toxic insults, maintaining normal fluid and electrolyte balance, and managing other complications of ARF as required. Because renal failure alters the metabolism and action of many drugs, often in ways that are not predictable, great care must be exercised in prescribing all medications. A compendium of guidelines for drug dosing in renal failure, such as the one by Brier and Aronoff, is of great help for this purpose.

After ensuring that the vital signs are adequate and that the patient is in no immediate danger from volume or metabolic derangements, the next step is to correct prerenal and postrenal factors, if any are identified. Intravascular volume should be replenished in hypovolemic patients and maintained in euvolemic patients by matching input to measured and insensible output. Inadequate cardiac output should be augmented when possible. Postrenal or obstructive ARF is treated by restoration of normal urine outflow. Bladder outlet obstruction may be relieved by passage of a Foley catheter, whereas upper tract obstruction may require percutaneous nephrostomy.

When prerenal and postrenal factors have been ruled out, the challenge to the emergency physician is to identify the cause of intrinsic renal ARF, keeping in mind the multitude of known possible causes (see Box 95-7). The clinical setting and physical and laboratory findings often allow the scope of the differential diagnosis to be considerably narrowed. The clinical picture is often most consistent with the broad category of ATN.

It has been noted repeatedly that patients who have oliguric ARF have a significantly higher mortality rate and a much greater risk of complications than those who are not oliguric. The difference in prognosis may simply reflect a more severe renal insult in patients who are oliguric, however, and it is not clear that interventions aimed at converting oliguric to nonoliguric ARF have an effect on renal function or mortality. Nevertheless, because nonoliguric patients are easier to manage, an attempt to increase urine flow is warranted.

Loop diuretics or mannitol often are effective in increasing urine flow when intravascular volume deficits have been corrected. Although furosemide has been shown to decrease dialysis requirements and complications caused by volume overload, it has not been shown to shorten the clinical course or affect mortality. Mannitol appears to be most useful when given at the time of or shortly after the renal insult; if urine output does not increase, further doses may cause hyperosmolality and clinically significant intravascular volume overload in patients with impaired renal function.

Dopamine also has been used, with and without furosemide, in an effort to increase urine output, but efficacy has not been validated in prospective studies.

Certain specific considerations apply to toxin-induced ATN. Pigment-induced ATN may be prevented by avoidance of hemolysis and muscle injury and by correction of the factors (e.g., dehydration, acidosis) that are known to predispose patients with pigmenturia to the development of renal failure. When hemolysis or rhabdomyolysis has occurred, treatment is directed at eliminating the cause and preventing the development of renal failure.

Mannitol has been shown to prevent ARF in experimental models of myoglobinuria, presumably by inducing osmotic diuresis and decreasing intratubular deposition of pigment. Furosemide, on the other hand, has not consistently shown a beneficial effect. Other studies have suggested that myoglobin precipitates in an acid urine but not in an alkaline urine. Thus, aggressive volume repletion, alkalinization, and mannitol infusion have traditionally been recommended after crush injuries to reduce the likelihood or severity of ARF. This regimen also helps control hyperkalemia. Other evidence, however, suggests that aggressive volume resuscitation alone may be equally effective. When ARF has occurred, management is similar to that of other forms of ARF, but early dialysis may be required to control rapidly developing hyperkalemia, hyperphosphatemia, and hyperuricemia.

Patients who have radiocontrast agent–induced ATN require only supportive therapy but should be hospitalized and seen by a nephrologist. A more significant aspect of ED management is preventing the occurrence of radiocontrast agent–induced ATN, particularly by identification of risk factors in patients for whom contrast studies are being considered. BUN and serum creatinine levels should be checked before contrast exposure in patients with risk factors. Moreover, before contrast medium is administered to a high-risk patient, it should be established that there is a compelling reason to perform the contrast study and that there is no adequate alternative to using a contrast agent. The patient should be volume-repleted before the study, the administered dose of contrast agent should be kept as low as possible, and multiple studies should be avoided, as should concomitant use of other nephrotoxins. Intravenous saline, given before and after radiocontrast agent administration, may be protective.

Volume and Metabolic Complications

In addition to those general measures aimed at minimizing decreases in GFR and increasing urine output, an important component of the management of ARF is the prevention or
control of systemic complications. Of particular significance in this regard are metabolic derangements (e.g., hyperkalemia, hypocalcemia, hyperphosphatemia, metabolic acidosis) and complications of volume overload (e.g., hypertension, CHF).

Hyperkalemia, the most common metabolic cause of death in patients with ARF, results from an inability to excrete endogenous and exogenous potassium loads. In oliguric patients the serum potassium level typically increases by 0.3 to 0.5 mEq/L per day, but greater increases occur in catabolic, septic, or traumatized patients and in the presence of acidosis or exogenous potassium loads from diet or medication.

Hyperkalemia results in serious disturbances in cardiac electrophysiology that may culminate in cardiac arrest. Although some hyperkalemic patients note muscular weakness, most generally are asymptomatic until major manifestations of cardio toxicity appear. Accordingly, detection of hyperkalemia should be a primary consideration in these patients. ECG changes correlate only roughly with the serum potassium level. Mild hyperkalemia (serum potassium less than 6.0 mEq/L) may be cautiously observed without specific treatment while all exogenous sources of potassium are eliminated. If the serum potassium level is greater than 6.5 mEq/L, and particularly if ECG changes are present, urgent intervention is necessary. When cardio toxicity must be reversed immediately (e.g., when there is hemodynamic compromise), intravenous calcium (10 mL of 10% calcium gluconate or calcium chloride infused over 2 minutes) is the treatment of choice. Intravenous insulin (given with glucose to prevent hypoglycemia) and intravenous bicarbonate temporarily shift potassium to the intracellular space. Bicarbonate should be used with caution in patients with renal failure because of its potential to cause volume overload and to provoke hypocalcemic tetany or seizures. The safety and efficacy of inhaled albuterol in hyperkalemic patients with chronic renal failure have been well documented; like insulin and bicarbonate, this agent causes potassium to move into cells, thereby controlling hyperkalemia for 2 hours or more. Elination of potassium from the body is promoted by using a potassium-binding ion exchange resin (sodium polystyrene sulfonate [Kayexalate]), by enhancing urinary potassium excretion, or by dialysis.

Hypocalcemia is a common feature of ARF and can develop rapidly after its onset. Vitamin D–dependent intestinal absorption of calcium is decreased in ARF because of decreased renal synthesis of 1,25-dihydroxyvitamin D. Another factor promoting hypocalcemia is the complexing of calcium with retained phosphate. Rhabdomyolysis-associated ARF in particular often is associated with the deposition of complexed calcium in muscle and other tissues. Asymptomatic hypocalcemia requires no immediate treatment, but subtle or frank tetany should be treated with intravenous calcium (10 to 20 mL of 10% calcium gluconate infused over several minutes).

Hyperphosphatemia resulting from decreased renal elimination of phosphate is another common feature of ARF. The serum phosphorus level usually ranges from 6 to 8 mg/dL but may be much higher with rhabdomyolysis or in catabolic states. A calcium-phosphate product greater than 70 may result in metastatic soft tissue calcification. Hyperphosphatemia often is treated with oral calcium-based antacids that bind ingested phosphate in the gut.

Acids produced in normal metabolic processes accumulate in ARF and are buffered in part by serum bicarbonate, resulting in a decrease in the serum bicarbonate level and a high-anion-gap metabolic acidosis. Compensatory hyperventilation may be mistakenly attributed to primary cardiac failure or volume overload. The metabolic acidosis associated with ARF usually is mild, and treatment generally is not necessary if the serum bicarbonate level is greater than 10 mEq/L. Overzealous correction may result in hypokalemia, hypocalcemia, or volume overload.

Hypermagnesemia may complicate ARF when patients are given magnesium-containing antacids or laxatives. Thus, these products, as well as magnesium itself (e.g., when given for treatment of arrhythmia or wheezing), should be avoided in the setting of ARF.

Disturbances of volume regulation can be expected to occur in most patients with ARF. Some nonoliguric patients excrete enough salt and water that intravascular volume depletion can occur if adequate fluid replacement is not provided. Volume depletion prolongs recovery from ARF. Much more commonly, ARF is complicated by volume overload, because sodium and water excretion may be inadequate to match even modest intakes. Volume overload is largely responsible for the hypertension often seen in ARF and commonly leads to CHF and pulmonary edema. Iatrogenic volume overload is particularly common and can be prevented only by careful attention to fluid intake and output using prudent estimates of insensible loss. Volume overload can be treated with diuretics or intravenous nitroglycerin while preparations are being made to initiate dialysis.

**Organ System Effects**

The clinician should be alert to the numerous other important systemic and organ-specific effects of renal failure. Only the more prominent of these are mentioned here.

Uremia impairs host defenses, particularly leukocyte function. Infection occurs in 30 to 70% of patients with ARF and is a significant cause of morbidity and mortality. Thus, patients with fever require prompt investigation and aggressive treatment.

Pericarditis, which has a prevalence of 12 to 20% in dialyzed patients with end-stage renal disease (ESRD), also may occur in patients with ARF. Chest pain that is worse in a recumbent position is the most common symptom, and most patients have a pericardial friction rub. Fever is common. The ECG may show ST-T wave elevation, low voltage, electrical alternans, or atrial fibrillation. The presence of pericardial effusion is identified most accurately by echocardiography; tamponade, with typical clinical signs, occurs in some patients. In contrast with the situation in chronic renal failure, pericarditis or pericardial effusion in the setting of ARF generally is an indication for the urgent initiation of dialysis. Patients who have hemodynamically significant tamponade require surgical drainage of the effusion or, occasionally, emergency pericardiocentesis.

Neurologic abnormalities in ARF may be precipitated by electrolyte abnormalities, medications, or uremia. Common signs and symptoms in uremic patients include lethargy, confusion, agitation, asterixis, myoclonus, and seizures.

Anorexia, nausea, vomiting, gastritis, and pancreatitis also are associated with ARF. GI hemorrhage is seen in 10 to 30% of patients and is one of the leading causes of death in ARF.

Impaired erythropoiesis, shortened RBC survival, hemolysis, hemodilution, and GI blood loss all play a role in the normocytic normochromic anemia that usually accompanies ARF. Although mild thrombocytopenia may be present, it is the qualitative defect in platelet function associated with ARF that is more significant and that contributes to these patients’ bleeding tendencies. In patients with active bleeding or those in whom an invasive procedure is being contemplated, the prolonged bleeding time can be corrected pharmacologically. Infusion of 10 units of cryoprecipitate normalizes the bleeding time in 1 to 2 hours, with a return to baseline in 24 hours. Administration of 1-deamino-8-D-arginine vasopressin (DDAVP) shortens the bleeding time within 30 minutes.
Patients with new-onset ARF should be hospitalized. If nephrology consultation and dialysis facilities are not available, transfer to another institution is advisable, once volume and metabolic abnormalities have been adequately controlled and the patient is hemodynamically stable.

Decisions regarding dialysis generally are made by the nephrology consultant and take into account many factors, including laboratory test result abnormalities and the presence or absence of signs and symptoms of uremia (e.g., nausea, vomiting, change in mental status). Many nephrologists choose to initiate dialysis when the BUN level exceeds 100 mg/dL or the serum creatinine level exceeds 10 mg/dL. Intractable volume overload and life-threatening hyperkalemia are the two most common indications for emergency dialysis.

**CHRONIC KIDNEY DISEASE**

In contrast with the typical patient with ARF, the patient with chronic kidney disease has most commonly experienced a slowly progressive course of decreasing renal function over months or years and is likely to have either slowly progressive symptoms or acute problems brought on by superimposed illness, trauma, or other physiologic stress. The most common problems requiring emergent intervention are severe hyperkalemia and symptomatic volume overload.

Barring renal transplantation, chronic kidney disease is an essentially irreversible condition generally characterized by a relentless decrease in renal function. Thus, whereas preservation of renal function may be a high priority in the patient with known ARF, management need not as a rule involve efforts to reverse the process presumed to have caused chronic kidney disease, nor even perhaps efforts to determine the exact cause. On occasion, however, the kidney disease may have a reversible component. In some cases, the underlying pathologic process affecting the kidneys may be arrested or treated; more commonly, correctable extrarenal factors (e.g., volume depletion or urinary tract obstruction) may be identified.

In the patient with chronic kidney disease who has an acute problem, the focus must be the identification and treatment of an intercurrent illness that has caused clinical decompensation, with the goal of returning the patient to a stable, chronically compensated status.

**Principles of Disease**

The standard terminology for chronic renal failure has changed. Chronic kidney disease denotes kidney damage or decreased renal function for 3 months or more and is characterized by irreversible nephron loss and scarring. Chronic renal insufficiency, which denotes kidney damage in which GFR has been moderately reduced but not to a degree sufficient to cause clear-cut clinical symptoms, has been replaced by an indication of the degree to which GFR is reduced. End-stage renal disease, now termed kidney failure, describes a condition in which renal function has diminished to a low level and in which serious, life-threatening manifestations can be expected to occur without dialysis or transplantation. At this stage, the kidneys often are shrunken and diffusely scarred to such a degree that it may be impossible to make an etiologic diagnosis, even on pathologic examination.

The causes of chronic kidney disease are numerous; their relative frequency depends primarily on the population studied. As with ARF, they can be conveniently classified (Box 95-9) as prerenal (vascular), intrinsic (glomerular and tubulointerstitial), or postrenal (obstructive). Glomerular disease accounts for approximately one third to one half of the cases of ESRD; in the United States, diabetic nephropathy forms the largest group of these. Hypertensive nephrosclerosis is another important cause, particularly among blacks, in whom it may be the cause of 25% or more of cases of ESRD. Among children and adolescents, reflux nephropathy is the most common cause of ESRD. Renal failure related to intravenous drug use or to human immunodeficiency virus disease is a major consideration in some populations. Clues to other specific causes may be gained from elements of the history, physical examination, or laboratory and imaging studies. Although determining the underlying cause of chronic kidney disease can permit the underlying disease to be treated and make possible some improvement in renal function in some cases, this is the exception rather than the rule.

**Uremia**

Progressive loss of renal function eventually results in a recognizable syndrome termed uremia. Clinical manifestations do not generally appear, however, until GFR has been reduced to approximately 15 to 20% of normal.

As the patient becomes unable to excrete an ingested salt or water load promptly, external balance of sodium and water...
is affected; volume overload or hypernatremia or hyponatremia may result. Inability to concentrate the urine is an early manifestation of renal insufficiency and may be manifested as nocturia. Potassium homeostasis is likewise disrupted, and a relatively small potassium load may lead to dangerous hyperkalemia. Acid-base balance is affected, because the kidney fails to clear the daily metabolic acid load owing to a decreased ability to excrete ammonium and phosphate; the result is a non-anion-gap acidosis in the earlier stages of chronic kidney disease and a superimposed anion-gap acidosis as GFR decreases further. Calcium and phosphate metabolism is affected as well; retention of phosphate and progressive loss of the kidney's capacity to synthesize 1,25-dihydroxycholecalciferol, the active form of vitamin D, lead to hypocalcemia, secondary hyperparathyroidism, and eventually the development of renal osteodystrophy.

Nitrogenous by-products of protein catabolism retained in the blood are the presumed cause of many of the diverse abnormalities of organ function in renal failure. Most patients with ESRD show decreased glucose tolerance, although it is rarely severe enough to require treatment unless the medical history includes established diabetes. In such cases, insulin or other hypoglycemic therapy may need to be continued but generally in a lower dosage than required before the onset of renal failure, because the normal kidney has a major role in insulin degradation. Alterations in lipid metabolism result in elevated low-density lipoproteins and hypertriglyceridemia in many patients with ESRD.

**Clinical Features**

Uremia has specific effects on a variety of organ systems. Many of these manifestations are relieved by dialysis, but others are not. A number have been attributed in some degree to the retention of nitrogenous wastes and to the previously noted derangements in vitamin D and parathyroid hormone metabolism.

**Cardiovascular**

The cardiovascular system is perhaps most dramatically affected in ESRD. Many of the manifestations can be attributed to the effects of chronic volume overload, anemia, hyperlipidemia, alterations in calcium and phosphorus metabolism, and volume- and hormonally mediated hypertension. Pericarditis, with or without pericardial fluid accumulation, also is common in ESRD, particularly among patients who have not had dialysis.

**Pulmonary**

Similarly, uremic pleuritis, with or without associated pleural fluid collections, may develop in some patients. So-called uremic lung, manifested radiographically by “batwing” perihilar infiltrates, represents pulmonary edema and is almost always caused by volume overload or myocardial dysfunction. Noninflammatory pleural effusion caused by volume overload also is fairly common. Of special importance in the ED evaluation is the fact that the radiographic appearance in pulmonary edema may at times be misleading, simulating an infectious lobar infiltrate or even assuming a nodular appearance in some cases.

**Neurologic**

Neurologic dysfunction is common in advanced uremia and usually is manifested by lethargy, somnolence, difficulty concentrating, or frank alteration in mental status. Seizures also may occur, although causes other than uremia alone must be ruled out. Uremic encephalopathy also is commonly manifested by hiccups, asterixis, or myoclonic twitching. The last should not be confused with tetany caused by hypocalcemia, which also is common in untreated patients with ESRD. In the peripheral nervous system, uremia often causes cramps and a distal sensorimotor neuropathy. A troublesome and characteristic complaint is “restless legs syndrome,” in which persistent neuropathic discomfort in the legs can be relieved only by movement.

**Gastrointestinal**

Anorexia, nausea, and vomiting are nearly constant features of uremia. These GI manifestations are thought to be caused by accumulation of nitrogenous wastes, because they often are relieved, even in the undialyzed patient, by introduction of a low-protein diet, and seem to correlate roughly with the BUN level.

**Dermatologic**

The skin of patients with chronic kidney disease has a characteristic yellowish tinge. “Uremic frost,” the result of deposition of urea from evaporated sweat on the skin, is a classic finding that, like “uremic fetor,” is seen only rarely now with the widespread use of dialysis (Fig. 95-4). Diffuse pruritus often is a major source of discomfort for the patient with ESRD; in some cases it may be caused by calcium deposition in the skin secondary to derangements in calcium metabolism.

The use of gadolinium-based contrast agents for magnetic resonance imaging (MRI) has been associated with the development of nephrogenic systemic fibrosis, a potentially fatal disorder of unknown etiology, in patients with chronic kidney disease.

**Musculoskeletal**

The bones and joints are sites of problems for many of these patients, particularly those with long-standing renal disease.

Figure 95-4. Uremic frost. Note the fine white powder on the skin of this patient with kidney failure.
The complex disturbances of calcium and phosphate metabolism in ESRD result in renal osteodystrophy, a clinical entity encompassing several overlapping varieties of bone disease that can cause bone pain or frank fractures. Patients with chronic kidney disease generally are treated with long-term oral calcitriol and vitamin D in an effort to prevent both secondary hyperparathyroidism and uremic osteodystrophy. Occasional patients will have a poor response to therapy and require parathyroidectomy.

A specific type of arthritis caused by deposition of calcium hydroxyapatite or calcium oxalate crystals in joints is seen in some patients, as are periarticular calcium deposition, spontaneous tendon rupture, myopathy, and carpal tunnel syndrome.

**Immunologic**

Infection remains a leading cause of death associated with renal failure. Uremic patients have long been noted to have an increased susceptibility to infection, even when not challenged by the invasive procedures associated with dialysis. Both humoral and cellular immunity have been shown to be affected. The relative importance of each in the pathogenesis of infection in renal failure has not been clarified, but defects in cellular immunity appear to be more significant clinically. Although patients with renal failure should be considered to be immunocompromised, most infections in patients with ESRD are caused by common pathogens rather than opportunistic organisms.

**Hematologic**

A rather severe normochromic normocytic anemia, with a hematocrit uncommonly in the range of 18 to 25%, is nearly universal in untreated ESRD, except among patients with polycystic disease. It is caused primarily by the kidneys’ decreased production of erythropoietin, a hormone that stimulates red cell production by the bone marrow. Other contributing factors are increased red cell hemolysis, nutritional deficiencies, and increased bleeding secondary to platelet dysfunction.

Although platelet number generally is normal in uremia, the bleeding time is prolonged because of defective platelet adhesiveness and activation. Numerous ecchymoses, seen in many patients with chronic kidney disease, is a common manifestation.

**Diagnostic Strategies**

The patient with chronic kidney disease, particularly one who is not yet receiving dialysis, is likely to present to the ED with one of the manifestations previously noted. In cases in which the diagnosis of renal failure has not previously been made, patients’ complaints most commonly are nonspecific and often of insidious onset, such as generalized weakness, poor appetite, or deterioration of mental functioning. The initial laboratory finding of a reasonably well-tolerated but rather severe anemia may be the first clue to the diagnosis, which is subsequently confirmed by elevated BUN and serum creatinine levels. A prudent next step is to check the ECG for evidence of immediately life-threatening hyperkalemia before further laboratory and radiographic investigations are undertaken.

Once it is determined that the patient is in no immediate danger, the ED evaluation should seek to establish that renal failure is indeed chronic rather than acute. An explicit history to that effect obtained from previous medical records or from the patient or family provides the most straightforward and reliable confirmation, as does the presence of a dialysis access device on physical examination. If such a history is unavailable, the finding of bilaterally small kidneys (readily detected on plain abdominal films or by ultrasonography) constitutes equally good evidence. However, the converse is not necessarily true—a finding of normal-sized or large kidneys does not rule out chronic kidney disease (Box 95-10). In such cases, additional diagnostic steps are required to establish the diagnosis. A convincing history of the long-standing presence of the presenting symptoms or of symptoms such as nocturia may be helpful in suggesting chronicity, as may a history of familial kidney disease such as polycystic kidney disease or Alport’s syndrome. Laboratory abnormalities such as anemia, acidosis, hyperuricemia, hypocalcemia, and hyperphosphatemia can occur in patients with acute kidney failure as early as 10 days after onset. Although urinary findings likewise tend not to be helpful, the presence of broad waxy casts on microscopic examination is suggestive of chronic disease, whereas the finding of an “active” sediment (e.g., red cell casts) is good evidence for an acute process.

Although as a rule chronic kidney failure is irreversible and slowly progressive, an essential component of the ED evaluation is to exclude the possibility of potentially reversible factors (in effect, ruling out “acute on chronic” renal failure), and to ensure that treatable causes of chronic kidney disease—disorders that if treated might allow for some return of renal function—have not been overlooked. These potentially reversible factors and treatable causes of chronic kidney disease are important to keep in mind because they represent the only potential opportunity to reverse the patient’s disease rather than simply to manage its results (Box 95-11).

Primary among superimposed reversible factors are those that lead to decreased renal perfusion. Of these, the most common is volume depletion. Regardless of the initiating cause, the process is exacerbated by the diseased kidney’s impaired ability to conserve sodium and to concentrate the urine appropriately. Decreased renal perfusion caused by cardiac dysfunction of any cause is another extremely common and potentially reversible factor. An uncommonly encountered but important vascular cause of reversible deterioration of renal function is scleroderma renal crisis, a syndrome of accelerated hypertension and severe vasoconstriction in patients with underlying scleroderma that can be reversed by timely treatment with ACE inhibitors.

Increased catabolism caused by infection, trauma, surgery, corticosteroids, or GI bleeding is another reversible factor that often is responsible for worsening azotemia and the development of uremic symptoms.

Drugs and toxins constitute another important group of reversible factors. Not only may these agents exacerbate renal insufficiency by causing intravascular volume depletion (diuretics), decreased renal perfusion (antihypertensive agents), or increased catabolism (tetracycline); they also can cause ATN (radiographic contrast material), AIN (many drugs), or inhibition of renal prostaglandin synthesis (NSAIDs).
Particularly noteworthy is the dramatic decrease in renal function produced when an ACE inhibitor is administered to a patient with renal insufficiency caused by bilateral renal artery stenosis (or renal artery stenosis in a solitary kidney).  

Postrenal reversible factors also are important because of their frequency, particularly obstructive disease in the older male patient and reflux nephropathy in the child. Papillary necrosis should remain a consideration in the diabetic patient, the patient with sickle cell disease, and the patient with a history of long-term analgesic use. Stone disease, retroperitoneal fibrosis, and even rarer entities such as ureteral tuberculosis also should not be overlooked.

Finally, treatment of the underlying disorder that has caused the chronic kidney disease can occasionally result in the return of some renal function, most notably in cases of myeloma kidney, some forms of secondary glomerulonephritis, and severe hypertensive disease. Although this consideration must relate to long-term care and follow-up, it is appropriate that ED management address this issue to ensure that appropriate evaluation and disposition are arranged.

Management

Persons with chronic kidney disease constitute a group of patients who merit special attention in the ED setting. These patients are susceptible to infection, bleeding, and the numerous other complications associated with renal failure, as well as those that may be associated with the underlying causative disorder. Moreover, these patients are more vulnerable to the effects of any intercurrent illness or trauma. Those who are maintained with chronic hemodialysis or peritoneal dialysis are subject to potential complications from the dialysis therapy itself.

Patients with chronic kidney disease also are uniquely susceptible to iatrogenic illness. First, they are less able to handle fluid and solute loads than are normal persons. Just as important, the presence of renal failure significantly alters the metabolism and action of many drugs, often in ways that are not predictable (Box 95-12). Thus, the dose and schedule of every administered agent, even apparently innocuous ones such as antacids, laxatives, antiemetics, or multivitamin preparations, should be carefully considered. For this purpose, ready access to a compendium such as the one by Brier and Aronoff or availability of a hospital pharmacist for frequent consultations is invaluable. In general, consultation with the patient’s nephrologist is recommended on completion of the initial ED evaluation, because management and follow-up monitoring after the patient leaves the ED often are complex.

In the United States, most patients with advancing chronic kidney disease eventually will require dialysis, but several true emergencies may develop in the patient with ESRD before chronic dialysis has been instituted. Specific diagnostic and therapeutic considerations apply to the management of these conditions regardless of whether they occur in dialyzed or undialyzed patients.

Hyperkalemia

Potentially the most rapidly lethal complication of chronic kidney disease encountered in the ED setting is severe hyperkalemia. As a rule, this condition is clinically silent until it causes potentially life-threatening manifestations. Accordingly, hyperkalemia must be looked for in every patient with chronic kidney disease. These patients can become severely hyperkalemic when required to handle even modest exogenous and endogenous potassium loads; moreover, even drugs that have only minimal effects on the serum potassium in normal persons, such as β-blockers and ACE inhibitors, can cause hyperkalemia in these patients. The inadvertent use of succinylcholine in patients with ESRD can rapidly result in life-threatening hyperkalemia.

An ECG should be obtained whenever hyperkalemia is a possibility, and if signs of hyperkalemia are noted, appropriate therapy should be started immediately, even before laboratory confirmation of a high serum potassium level. ECG changes may be completely absent even when hyperkalemia is severe, however. Thus, a normal ECG does not preclude the need for laboratory confirmation of a normal serum potassium level. A potassium level of 6 mEq/L should be considered potentially dangerous, even though many patients with ESRD chronically tolerate levels somewhat above this threshold without ECG changes. A patient with chronic kidney disease who is in cardiac arrest should be assumed to be hyperkalemic and treated accordingly while the usual resuscitative measures are taken.

The most rapidly effective treatment for hyperkalemia is intravenous calcium, which transiently reverses the cardiac manifestations of hyperkalemia without altering the serum potassium level or total-body potassium (Table 95-3). Calcium should be given to buy time in which more definitive measures can take effect. It makes little sense to administer calcium in
response to an elevated serum potassium level in the absence of manifestations of hyperkalemia on the ECG.

In treating hyperkalemia, it also is important to keep in mind the ESRD patient’s limited ability to tolerate volume and solute loads (see Table 95-3). Thus, repeated doses of intravenous sodium bicarbonate risk causing volume overload and precipitating pulmonary edema. Intravenous glucose and insulin act less rapidly and also entail volume administration. If the patient’s condition permits, however, the latter method is preferred because sodium administration can be avoided and hyperkalemia can be controlled for as long as the infusion is continued. Another effective temporizing measure is the administration of inhaled albuterol to promote movement of potassium into cells while more definitive maneuvers are being instituted.51,52

To remove potassium from the body, sodium polystyrene sulfonate (Kayexalate), a resin that exchanges sodium for potassium ions, can be administered orally or rectally. This drug can continue to control the potassium for hours and, despite the modest sodium load it entails, can be effective as a temporizing measure until dialysis (if necessary) can be instituted.53

In light of the potential for ototoxicity with the use of loop-diuretics, these drugs should be administered by slow infusion rather than by bolus. They probably should be avoided in patients who also are receiving other potentially ototoxic agents. During the course of any of these therapeutic interventions, both the ECG and serum potassium levels must be monitored frequently.

**Pulmonary Edema**

Perhaps the most common ED problem in patients with chronic kidney disease is pulmonary edema secondary to volume overload. Surprisingly, the diagnosis is not always straightforward. The history may be suggestive of increasing dyspnea on exertion or paroxysmal nocturnal dyspnea, but physical examination may not reveal the expected signs of CHF, and even chest radiography may be deceptive54 (Fig. 95-5). Recent weight gain or a body weight considerably over “dry weight” (typically more than 5 pounds) is the most reliable clue, and in the absence of convincing evidence of another cause for dyspnea, volume overload should be assumed to be the cause and the patient should be treated accordingly.

patient is hypertensive. Intravenous morphine increases venous capacitance, but as in patients without renal failure, its routine use as a first-line drug in pulmonary edema has become less common. Diuretics are not expected to be helpful unless the patient has retained a significant level of renal function.

**Infection**

Because infection is a major contributor to morbidity and mortality among patients with ESRD, the possibility of serious infection should be entertained even when the expected classic findings are not all present. For example, bacteremia may be manifested by fever alone, just as it is in other patients with impaired immunity. Patients with pneumonia may present with only vague dyspnea or malaise, symptoms that may be attributed to volume overload or uremia. Thus, all diagnostic possibilities should be pursued, and empirical broad-spectrum antibiotic coverage often is advisable until infection has been ruled out in the hospital. Bacteremia resulting from vascular access infection is quite common in patients receiving hemodialysis, as is peritonitis in patients undergoing peritoneal dialysis.

UTI can occur even in patients with minimal urine output or those with long-standing renal failure. Urinary stasis is undoubtedly a predisposing factor.

The two major dialysis modalities are hemodialysis and peritoneal dialysis. Each is based on technology wherein the patient’s blood comes into contact with a semipermeable membrane on the other side of which is a specially constituted balanced physiologic solution. Water and solutes diffuse across the membrane by moving along concentration and osmotic gradients, effectively normalizing the blood’s composition.

**Dialysis**

Dialysis can normalize fluid balance, correct electrolyte and other solute abnormalities, and remove uremic toxins or drugs from the circulation when the patient’s kidneys are unable to do so. Dialysis also can, but generally to a lesser degree, reverse some uremic symptoms and permit better long-term control of hypertension, anemia, and renal osteodystrophy.

The two major dialysis modalities are hemodialysis and peritoneal dialysis. Each is based on technology wherein the patient’s blood comes into contact with a semipermeable membrane on the other side of which is a specially constituted balanced physiologic solution. Water and solutes diffuse across the membrane by moving along concentration and osmotic gradients, effectively normalizing the blood’s composition.

Hemodialysis requires special access to the patient’s circulation, generally through a surgically created arteriovenous fistula or implanted artificial graft, or through a surgically placed tunneled catheter. The vascular access site must be treated with care because hemodialysis cannot be performed without it. Careless manipulation or puncture can result in bleeding, infection, or thrombosis that may result in loss of the access. The involved arm should not be used for blood pressure determinations, and a tourniquet should not be applied.

In general, blood should be drawn and intravenous lines established in other locations. In exceptional circumstances, if no other site is available and it is essential to obtain blood samples quickly, the fistula or graft may be used, but with precautions: A tourniquet should not be applied, the area should be cleansed scrupulously before the puncture, and extreme care should be taken not to puncture the back wall of the access opening. After the puncture, firm but nonocclu-
Indications for emergency dialysis

The decision to initiate chronic dialysis in the patient with ESRD generally is made by the patient’s nephrologist in the setting of gradually decreasing GFR and slowly progressive manifestations of renal failure. The absolute value of the BUN or serum creatinine generally is used only as a rough guide to when chronic dialysis should be instituted. Provision of vascular or peritoneal access usually has been arranged weeks to months before the anticipated initiation of dialysis, to allow the access site to mature and to minimize any mechanical complications of the procedure.

For patients who come to the ED with ARF, however, as well as for patients with chronic kidney disease in whom acute problems have developed, it is the emergency physician who must be prepared to make the decision to arrange for dialysis to be provided emergently (Box 95-14). How urgently dialysis must be initiated depends on not only the severity and acute- ness of the presenting problem but also on the availability of technical facilities and trained dialysis personnel and the effectiveness of available temporizing measures for the problem at hand.

The most common problem requiring emergent dialysis, particularly in the patient with ESRD, is pulmonary edema secondary to volume overload. Generally, the inciting cause is overinjection of fluid and salt in excess of the patient’s greatly diminished renal excretory capacity. Despite the effectiveness of temporizing measures, many of these patients require immediate dialysis—either emergency hemodialysis or, in the case of the patient maintained on peritoneal dialysis, intensification of the usual dialysis regimen.

A related problem that may require emergent, or at least urgent, dialysis is malignant hypertension, particularly when associated with hypertensive encephalopathy or cardiovascular decompensation. Because hypertension in most patients with renal failure commonly is volume-dependent, correction of volume overload, even if clinically inapparent, is a central component of therapy. Temporizing measures such as the administration of intravenous sodium nitroprusside or nitroglycerin often permit hypertension to be controlled sufficiently that dialysis can be delayed for several hours, but prolonged administration of sodium nitroprusside carries an increased risk of thiocyanate toxicity in patients with renal failure. In many cases, hypertension and associated symptoms are difficult to control until dialysis permits volume overload to be corrected. Because the blood pressure often is dramatically responsive to reduction of circulating volume, it is recommended that other antihypertensive agents with more prolonged effects be withheld until after dialysis has been able to reduce circulating volume.

Severe hyperkalemia is another common indication for emergent or urgent dialysis, particularly in the patient with ARF who is hypercatabolic. In the patient with chronic kidney disease, hyperkalemia usually is caused by excessive potassium intake, but endogenous causes such as hemolysis or rhabdomyolysis must be kept in mind as well. A variety of available temporizing measures can be used with variable degrees of effectiveness and for different durations to control the serum potassium level, but dialysis remains the most effective means of removing potassium from the body. For rapid control of the serum potassium, hemodialysis, with its high clearance rates, is preferred to peritoneal dialysis.

Other severe electrolyte and acid-base disturbances, including diabetic ketoacidosis, may sometimes necessitate emergent dialysis. Occasional patients with renal failure and severe hypercalcemia uncontrollable by other modalities (e.g., patients with multiple myeloma causing both renal failure and hypercalcemia) may require dialysis. The occasional patient with renal failure in whom severe hypermagnesemia develops after inappropriate therapy or magnesium ingestion may require immediate dialysis to reverse life-threatening paralysis or cardiac dysrhythmia. Severe metabolic acidosis in the setting of renal failure is another indication for emergent dialysis, particularly if volume overload precludes the administration of reasonable amounts of bicarbonate. Of note, bicarbonate also can precipitate tetany and convulsions if administered intravenously (e.g., to treat acidosis or hyperkalemia) to a patient with hypocalcemia.

A somewhat unusual but related situation is one in which a patient with renal failure has taken an overdose or inadvertently been administered medication that ordinarily is cleared by the kidneys. If the agent is adequately dialyzable and its continued presence in the circulation poses a significant risk to the patient, immediate dialysis can be lifesaving. An example of such a situation is the ingestion of methanol or ethylene glycol by a dialysis patient. Similarly, ill-advised use of magnesium-containing cathartics or phosphate-containing enemas by patients with ESRD can lead to dangerous hypermagnesemia and hyperphosphatemia, respectively, and may necessitate urgent dialysis.

The serum creatinine and BUN levels themselves should not be considered indications for dialysis. A creatinine of 10 mg/dL or a BUN of 100 mg/dL often is used as a guideline for beginning chronic dialysis in the patient with progressive renal failure. In dialyzed patients, however, the serum creatinine often is considerably greater than 10 mg/dL but is a reflection more of total body muscle mass than the adequacy of dialysis. The BUN is a somewhat better indicator; the level in well-dialyzed persons generally is in the range of 50 to 80 mg/dL and is more than 100 mg/dL in less well-dialyzed patients. Neither blood level, however, correlates more than roughly with uremic symptoms even in undialyzed patients or

**Box 95-14 Indications for Emergency Dialysis**

- Other severe electrolyte or acid-base disturbances
- Some overdoses
- Pericarditis (possibly)
has any direct bearing on how urgently dialysis should be initiated.

The occurrence of uremic symptoms or signs such as nausea, vomiting, lethargy, or twitching indicates a need for dialysis but does not necessitate immediate initiation of dialysis unless symptoms are severe. Pericarditis, even in the absence of cardiac tamponade, often is considered an indication for urgent dialysis, but it is not uncommon for pericarditis to occur in well-dialyzed ESRD patients as well. In a previously undialyzed patient with progressive renal insufficiency, the appearance of pericarditis indicates that it is time to initiate dialysis, although not necessarily on an emergency basis.

Complications of Dialysis Therapy

Optimal ED management of acute problems referred from the dialysis unit, or those occurring at home or in the interdialysis period, requires knowledge of and familiarity with the particular problems associated with ESRD and dialysis. Consultation with the nephrologist or dialysis nurse is important in arranging a consistent care plan for the dialysis patient with an emergent condition and in ensuring appropriate further acute care or follow-up monitoring.

Complications of Hemodialysis

Vascular Access–Related Complications. The performance of hemodialysis depends on reliable vascular access, and it is the vascular access device that is responsible for complications of dialysis that most often require evaluation in the ED setting. These problems must be attended to promptly to minimize the risk of losing the patient’s dialysis “lifeline.”

Bleeding from the dialysis puncture site can occur hours after a hemodialysis treatment, either spontaneously or after inadvertent minor trauma to the site. Such bleeding almost always can be stopped by applying firm pressure to the access site; care should be taken not to occlude and possibly cause thrombosis of the vessel by compressing it too vigorously, and the presence of a thrill immediately after the procedure should be documented on the chart. It may be necessary to keep the patient in the ED for a time to ensure that bleeding does not recur. Recurrent bleeding, especially from an aneurysm or a pseudoaneurysm, should be evaluated by a vascular surgeon.

Similarly, if the patient reports that the thrill in the access has been lost, a vascular surgeon should be consulted immediately. Although thrombolytic agents sometimes are used, definitive treatment generally is surgical revision. The access device should not be forcefully manipulated or irrigated, because rupture of the vessel or venous embolization may result.

Infection of the vascular access is not uncommon and can result in persistent or recurrent bacteremia as well as loss of the access. Infection appears to be a consequence of contamination at the time of puncture for dialysis; most infections are caused by staphylococci typical of skin flora. Infections are more likely to occur in grafts than in native fistulas. The signs and symptoms of an access infection—redness, warmth, and tenderness over the site—are obvious, but in many cases, localizing findings are absent and the patient has only a fever or a history of recurrent episodes of fever and documented bacteremia. For this reason, it is common practice to obtain blood cultures for all patients on hemodialysis who have a fever without an obvious source of infection and to treat them presumptively for an access infection. A careful search for other sources of infection should be made, however, before that inapparent access infection is concluded to be the cause. Infections such as odontogenic abscess, extremity cellulitis (particularly in diabetics), and perirectal abscess can easily be missed.

Although some nephrologists prefer to admit all dialysis patients with fever to the hospital, management of these patients on an outpatient basis often is possible, provided that they otherwise feel well and do not appear to be septic and provided that they can care for themselves at home and return promptly if their condition worsens. This course is more practicable by the fact that they can be loaded with intravenous antibiotics that dependably maintain adequate blood levels until the time of the next scheduled dialysis treatment, at which time the culture and sensitivity test results can be checked and therapy adjusted accordingly. Vancomycin 1 to 1.5 g given intravenously as a single loading dose is the drug of choice in this situation, because most access infections are staphylococcal and because this drug is only minimally hemodialyzable and needs to be given only every 5 to 7 days in the chronic dialysis patient. If a gram-negative infection also is thought to be likely, as in a patient who has had recent episodes of gram-negative bacteremia, a loading dose of a second drug (e.g., a third-generation cephalosporin or an aminoglycoside) also can be administered. Patients can be reloaded with these drugs at the end of their next hemodialysis session if culture results prove to be positive.

Non–Vascular Access–Related Complications. The hemodialysis procedure itself, which entails invasion of the vasculature, anticoagulation, and often massive shifts of fluid and solutes, often is associated with acute complications such as hypotension, shortness of breath, chest pain, and neurologic abnormalities.

Hypotension. Hypotension that occurs after dialysis is most commonly the result of an acute reduction in circulating intravascular volume and the failure of the patient’s homeostatic mechanisms to compensate for it. Because hemodialysis is episodic, each treatment must remove the excess fluid that has accumulated over the period since the last dialysis (generally 2 to 3 days), and patients often are relatively volume-overloaded at the beginning of each treatment. With rapid removal of extracellular fluid, there is inadequate time for transcellular fluid shifts to replace intravascular volume. Antihypertensive medications, particularly β-blockers, that are required when the patient is in a volume-expanded state, can contribute to the hypotension when intravascular volume is normalized.

Most episodes of hypotension that occur during hemodialysis will resolve spontaneously or can be readily managed by either a decrease in blood flow rate or the infusion of small volumes of saline (to effect transient volume expansion) or hypertonic solutions (to reverse transiently acute hyponatremia). Patients with significant hypotension who do not respond to these maneuvers often are brought to the ED for further evaluation. Patients on dialysis should be considered to be at risk for acute myocardial infarction, acute dysrhythmias, and sepsis. These are common causes of hypotension among all patients presenting to the ED, and consideration should first be given to these entities (Box 95-15).

Acute hemorrhage also is not uncommon in dialysis patients. Almost all of these patients are now routinely treated with epoetin or darbepoetin to prevent severe anemia, but untreated patients typically have low baseline hemoglobin levels, and acute blood loss may result in symptomatic angina or CHF. Serum levels of clotting factors are normal in ESRD, but patients are routinely anticoagulated for each hemodialysis treatment. Although transient thrombocytopenia may occur during the dialysis procedure, the qualitative platelet defect characteristic of renal failure represents the most important factor in bleeding that continues beyond the peridialytic period. This abnormality is only partially reversed by dialysis but can be corrected by administration of DDAVP, which

- Dialysate-related
- Autonomic neuropathy
- Excessive access arteriovenous flow
- Anaphylactoid reaction
- Air embolism

increases release of factor VIII–von Willebrand factor (VWF) polymers from vascular endothelium. DDAVP has been used successfully to normalize the bleeding time in preparation for surgery in patients with chronic kidney disease. Cryoprecipitate and conjugated estrogen both have been shown to produce similar effects for a longer period.32

Overt bleeding from the GI tract, often caused by angiodysplasia or peptic ulcer disease, is common and can be dramatic. Occult hemorrhage in other locations, however, can present a diagnostic challenge, because symptoms and signs of volume loss tend to be overshadowed by local manifestations of bleeding into a closed space. Thus, spontaneous retroperitoneal or pleural hemorrhage tends to manifest with flank pain or with chest pain and shortness of breath, respectively.

Occasionally, acute hypotension may be caused by anaphylaxis or an anaphylactoid reaction to some component of the dialyzer or the dialysate; these possibilities should be considered if the history is suggestive. Acute pulmonary embolism and acute air embolism are two less likely possibilities. The former, although it does occur occasionally in dialysis patients, is unusual. The latter, although reported occasionally in the past, has been all but eliminated by improved dialysis monitoring equipment and safety mechanisms.

Two additional entities in the differential diagnosis for hypotension are of particular importance in the patient with ESRD—acute pericardial tamponade and severe, life-threatening hyperkalemia. Acute pericardial tamponade may be the result of either sudden pericardial hemorrhage or sudden worsening of a formerly compensated pericardial effusion after acute correction of elevated preload. The clinical features of tamponade in the dialysis patient are similar to those in other populations, but the common preexistence of cardiomegaly may make the chest film difficult to interpret unless it shows the typical “water bottle” shape and a definite increase in heart size from previous examinations.

Similarly, an elevated central venous pressure is of little use in differentiating tamponade from underlying right-sided heart failure. Even a bedside ultrasonographic examination that shows pericardial fluid, although suggestive, is not proof that tamponade is present, because many dialysis patients chronically have pericardial effusions that do not cause hemodynamic compromise.78,79 Ultrasonographic demonstration of right ventricular diastolic collapse is more specific, but a definitive diagnosis of tamponade depends on the direct demonstration of equal pressures in the right and left atria on cardiac catheterization.

Emergency pericardiocentesis must occasionally be performed in the ED to relieve acute tamponade, but there often is enough time for the patient to be transported to the catheterization suite or operating room for safer and more definitive therapy in a controlled setting. If immediate pericardiocentesis is believed to be necessary, however, the emergency physician should not hesitate to perform this potentially lifesaving procedure, despite the many potential complications and the increased risk of bleeding in patients with ESRD. Similarly, in the case of a dialysis patient who is in cardiac arrest, pericardiocentesis generally should be attempted if initial resuscitative efforts have not been successful.

Severe, life-threatening hyperkalemia, although unusual in a dialyzed patient, can occur in the presence of underlying catastrophic illness or with a prolonged period of hypotension and low flow. Patients who are hyperkalemic can have profoundly slow heart rates, particularly if they have been treated with β-blockers or calcium channel blockers. If a dialysis patient is in cardiac arrest, it should be assumed that hyperkalemia is present, and intravenous calcium should be given immediately.

Shortness of Breath. Shortness of breath in dialysis patients generally is caused by volume overload. In the patient who becomes short of breath while being dialyzed, however, other causes must be sought—primarily sudden cardiac failure, pericardial tamponade, pleural effusion or pleural hemorrhage. Air embolism and anaphylactoid reactions are unusual causes. Often, pneumonia or underlying reactive airway disease is responsible.

Chest Pain. Chest pain during dialysis must be taken seriously because cardiovascular disease is a leading cause of death in patients with ESRD, and most episodes of chest pain occurring during dialysis are likely to be ischemic in origin.53,84 Most dialysis patients have risk factors for coronary artery disease, related to either ESRD itself or the underlying condition that led to renal failure, and many have well-documented coronary artery disease.84 ESRD commonly is associated with hypertension, hyperlipidemia, carbohydrate intolerance, and disturbances of calcium and phosphorus metabolism. In addition, dialysis patients may be anemic, and many are chronically volume-overloaded. During hemodialysis, these underlying factors may be added to acute physiologic stresses such as transient hypotension and hypoxemia, which often are associated with the dialysis procedure, thereby increasing myocardial oxygen demand while decreasing oxygen delivery.

In evaluating presumed ischemic chest pain in a patient with ESRD, it is important to keep in mind the potentially reversible factors that may have precipitated the episode. Particularly when a patient whose angina has been stable begins to experience more frequent or more severe anginal episodes, it should be determined whether increasing anemia, poorly controlled hypertension, or uncorrected volume overload is a factor. Coronary artery disease appears to become symptomatic with a lesser degree of obstruction than that in other etiologic conditions.

Patients who repeatedly experience chest pain during dialysis should undergo a complete evaluation so that the extent of their coronary artery disease can be defined and optimal management planned. After repeated, frequent hospital
admissions to rule out myocardial infarctions because of chest pain during dialysis, it may be reasonable for the patient’s nephrologist and cardiologist to set guidelines regarding further admissions.

The presence of renal failure and its associated electrolyte and acid-base disturbances does not in general obscure the usual ECG changes of angina or acute myocardial infarction. The pattern of the change of serum cardiac enzymes with acute infarction also is not altered by ESRD, although the baseline level of these enzymes may be higher than in the general population. Troponin appears to perform best as a marker of infarction in patients with ESRD. Treatment of ischemic chest pain is the same as for other populations.

Among nonischemic causes of chest pain, pericarditis should always be a consideration, even in the well-dialized patient. The presentation is essentially the same as in nonrenal patients; fever, a friction rub, or atrial dysrhythmias may be associated findings, and signs of pericardial effusion or early tamponade should be sought. Indomethacin often is effective in relieving pain, but some patients eventually require further measures, such as pericardiocentesis with corticosteroid instillation or pericardial stripping. Patients with pericarditis often receive more frequent or intensified dialysis, because pericarditis is thought to be a marker for inadequate dialysis.

Neurologic Dysfunction. Neurologic dysfunction manifesting during or immediately after hemodialysis often is caused by disequilibrium syndrome, a constellation of symptoms and signs that is thought to be due to rapid changes in body fluid composition and osmolality during hemodialysis. It usually occurs only in patients with high BUN levels who are just starting hemodialysis. The syndrome does not occur with peritoneal dialysis. Typically, patients have headache, malaise, nausea, vomiting, and muscle cramps, but features in more severe cases may include altered mental status, seizures, or coma. Symptoms resolve over several hours as fluid and solutes are redistributed across cell membranes.

It is dangerous, however, to attribute an altered mental status to disequilibrium syndrome unless other potential causes have been ruled out (Box 95-16), particularly when symptoms persist, fluctuate, or worsen during a reasonable period of observation. Likewise, when seizures occur during dialysis, it is tempting but unwise to attribute them to disequilibrium syndrome without considering other, potentially serious causes, even in patients who have had seizures in the past. In particular, the finding of any new focal neurologic abnormality calls for, at a minimum, an immediate head CT scan to detect intracranial hemorrhage. Similarly, if fever or other evidence of infection is present, meningitis must be a serious consideration. Other considerations include hyperglycemia and hypoglycemia (especially in the diabetic patient), electrolyte abnormalities, hypoxic states, hypotension of any cause, and other toxic or metabolic causes. The treatment of seizures in patients with ESRD is essentially the same as in other populations.

Complications of Peritoneal Dialysis

As with hemodialysis, most of the complications of peritoneal dialysis are related to the dialysis access device, in this case the peritoneal catheter. In contrast with hemodialysis, however, the dialytic process in peritoneal dialysis occasions few immediate difficulties. Whatever volume or metabolic problems develop often are a consequence of the fact that the typical patient maintained on peritoneal dialysis is seen by a doctor or nurse only once a month.

Peritonitis is the most common complication of peritoneal dialysis. Fortunately, it is in general much less severe than other types of peritonitis and can be treated readily on an outpatient basis despite the continued presence of a foreign body—the Tenckhoff catheter—in the peritoneal cavity. Occasionally, when an episode of peritonitis responds poorly to antimicrobial therapy or when a patient has repeated episodes of peritonitis caused by the same organism, the catheter must be removed and the patient sustained with hemodialysis until the infection is completely cleared and a new catheter can be placed. Repeated infections do, however, carry the risk of permanently altering peritoneal permeability or effective surface area and necessitating a permanent switch to hemodialysis.

Peritonitis in patients on peritoneal dialysis presumably is caused by inadvertent bacterial contamination of the dialysate or tubing during an exchange or by extension of an infection of the exit site or the subcutaneous tunnel into the peritoneal cavity. A majority of cases of peritonitis are caused by Staphylococcus aureus or Staphylococcus epidermidis, and most of the remainder (approximately 20%) by gram-negative enteric organisms. Fungal infections are uncommon but generally are refractory to medical therapy and often are considered an indication for catheter removal. Polymicrobial infection suggests direct contamination from the GI tract and mandates a search for the site of perforation or fistula, although such a source is identified in only a minority of cases. No organism is identified in approximately 10 to 20% of cases of peritoneal dialysis–associated peritonitis.

The diagnosis of peritonitis usually is made by the patient when a cloudy dialysate effluent is noted, corresponding with the appearance of WBCs in the dialysate. Peritonitis often, but by no means invariably, is accompanied by nonspecific abdominal pain, malaise, or fever. Even in the absence of cloudy fluid, when a patient has fever or abdominal symptoms, it is advisable to consider peritonitis and to check the fluid, because early peritonitis may manifest atypically. In more severe cases, peri- tonitis is accompanied by nausea, vomiting, severe pain, and hypotension, necessitating hospitalization and consideration of the possibility of acute surgical disease.

In the ED setting, the diagnosis of peritonitis is confirmed by the finding of more than 100 WBCs/mm³ in the peritoneal

| DIFFERENTIAL DIAGNOSIS OF ALTERED MENTAL STATUS IN DIALYSIS PATIENTS |

|                          | Hypoxemia           |
|                          | Dialysis dementia   |
fluid, with more than 50% neutrophils, or by a positive result on Gram staining. A sample of fluid should be obtained for analysis, preferably by a specialized dialysis nurse, if available. Fluid should be sent for cell count and differential, Gram's staining, and culture (using blood culture bottles).

Peritoneal dialysis–associated peritonitis usually can be treated with an initial intraperitoneal loading dose of antibiotic, followed by a 10- to 14-day course of intraperitoneal antibiotics, of which some may be administered by the patient on an outpatient basis. After the diagnosis has been confirmed, consultation with the patient’s nephrologist or dialysis nurse specialist is indicated to determine antibiotic therapy as well as a plan for outpatient management and follow-up evaluation or occasionally, if peritonitis is severe or if outpatient management is precluded by psychosocial considerations, for hospitalization.

A common treatment regimen is a loading dose of vancomycin 30 mg/kg given intraperitoneally (IP), followed by further intraperitoneal doses every 4 to 7 days, plus ceftazidime or cefepime 1 g IP or gentamicin 0.6 mg/kg IP. The latter two regimens are given as a loading dose followed by maintenance doses administered intraperitoneally once daily at the time of an exchange. Heparin 500 to 1000 units also may be added to each bag of dialysate for the first few days of treatment to help reduce the formation of fibrin strands that may obstruct the catheter. Patients should be seen by the dialysis nurse in 24 to 48 hours to check on the response to therapy and to adjust antibiotic therapy as necessary after reviewing the results of culture and sensitivity testing.

Catheter contamination or leaks from the catheter, tubing, or dialysate bag should be managed in the same fashion as for frank peritonitis. The site and cause of leakage should be identified, and damaged elements should be replaced promptly. Occasionally, with leakage of peritoneal fluid from around the catheter, surgical correction of the underlying problem will be necessary.

Patients who have severe abdominal pain, vomiting, ileus, chills or high fever, or hypotension should be hospitalized. Likewise, patients with severe underlying illness and those who cannot reliably perform exchanges or administer antibiotics at home require inpatient management. Dialysis exchanges should be continued on the same schedule. The inpatient antibiotic regimen is essentially the same as that used for outpatients.

Perhaps the most serious potential pitfall in caring for the patient maintained on peritoneal dialysis with abdominal pain or other signs of peritonitis is to overlook other serious intra-abdominal conditions whose presentation may mimic that of peritonitis. Patients on peritoneal dialysis are at increased risk for abdominal wall or inguinal hernia because of chronically increased intra-abdominal pressures; previous abdominal surgery also places them at risk for hernia, as well as for obstruction secondary to adhesions. The manifestations of serious disorders unrelated to dialysis (e.g., acute appendicitis, diverticulitis, cholecystitis, acute pancreatitis, ischemic bowel, perforated viscus) also may be attributed to ordinary peritoneal dialysis–associated peritonitis, with the potential for disastrous consequences. The accessibility of the peritoneal fluid for examination may prove to be helpful in documenting the presence of an inflammatory process, but it also has the potential to mislead ED investigation of its cause. A finding of brownish or fecal material in the peritoneal drainage should suggest a ruptured viscus until proven otherwise, and immediate surgical consultation should be sought. Detection of localized terness, a palpable mass, or an incarcerated hernia on physical examination can be extremely helpful in making the diagnosis. Abdominal radiography may be useful for demonstrating the presence of ileus, but pneumoperitoneum may reflect only the introduction of air during a recent fluid exchange rather than a perforated viscus. Thus, it is important to keep in mind the possibility that disorders other than peritonitis may underlie the patient’s symptoms, and astute clinical judgment rather than specific criteria should dictate requests for surgical consultation or decisions regarding hospitalization of the patient for observation.

Infection of the catheter exit site is another relatively common problem for which the patient on continuous ambulatory peritoneal dialysis may seek care in the ED. This infection tends to be caused by typical skin flora and is manifested by the usual local signs of infection. Although not serious in themselves, exit site infections should be taken seriously because they may lead to infection of the subcutaneous tunnel, which can cause repeated episodes of peritonitis and may ultimately necessitate removal of the catheter. Any visible exudate should be cultured and Gram stained, and therapy with an oral antibiotic such as trimethoprim-sulfamethoxazole should be started, pending the results of culture and sensitivity testing. The patient should be instructed to cleanse the site meticulously several times a day using povidone-iodine or peroxide solution.

Tunnel infections can be difficult to detect on physical examination and may be suspected only after the patient has several bouts of peritonitis caused by the same organism. As with other closed-space infections, they tend to be difficult to eradicate unless the tunnel is partially unroofed and drained.

Patients maintained on peritoneal dialysis also may present to the ED with any of several basically mechanical problems, of which the most common is failure of the dialysate to drain completely at the time of an exchange. Occasionally, this problem is caused simply by kinking or inadvertent clamping of the external catheter or tubing, but more often it is the result of catheter obstruction by fibrinous debris or kinking or migration of the catheter within the peritoneal cavity, often associated with constipation. Catheter position is best assessed initially by plain radiography of the abdomen. Specific intervention may be guided by a contrast “catheterogram.” Fibriolytic agents have been used successfully to open occluded catheters, but surgical intervention for catheter replacement often is required.

Severe metabolic disturbances are much less common among patients on peritoneal dialysis than patients on hemodialysis, because in the former group, dialysis is being performed essentially continuously and the blood remains in near-equilibrium with the dialysate. Significant disturbances do occasionally occur, usually in association with hypercatabolic states, major dietary indiscretions, or significant GI fluid loss. One interesting derangement that occurs occasionally in diabetic patients receiving peritoneal dialysis is a syndrome of severe hyperglycemia (sometimes even despite continuation of the usual insulin dose) resulting from absorption of glucose from hyperosmolar dialysate, with associated nonspecific symptoms of malaise, weakness, and headache. Although glucose levels may be as high as 1500 mg/dL in these patients, they cannot undergo an osmotic diuresis and remain clinically euclidean. Correction of hyperglycemia must be undertaken carefully to avoid causing rapid osmolar and volume shifts.
KEY CONCEPTS

Acute Renal Failure
- The causes of ARF can be classified as prerenal, postrenal, and intrinsic renal disorders.
- Management of ARF should be directed first at potentially lethal complications such as hyperkalemia or volume overload and then at reversal of the underlying cause of renal dysfunction. It is important to avoid any further hemodynamic or toxic insults to the kidneys.
- The patient’s impaired renal function must be considered when fluid is administered and drugs are prescribed.

Chronic Kidney Disease
- Patients with chronic kidney disease have a limited ability to handle fluid and solute loads and have altered metabolism of many drugs; therefore, as with ARF, fluid administration regimens and drug dosages should be checked carefully.
- The most rapidly lethal complication of chronic kidney disease is hyperkalemia. The possibility of this entity should always be considered, and appropriate diagnostic and therapeutic interventions should be instituted when indicated.
- Patients with renal failure often present with varying degrees of volume overload. Volume overload generally should be the first diagnostic consideration when dyspnea is the presenting complaint.

CHAPTER 96  Sexually Transmitted Diseases

Diane M. Birnbaumer and Christine Anderegg

PERSPECTIVE

More than 300 million new cases of curable sexually transmitted diseases (STDs) are diagnosed worldwide each year, and these cases frequently are seen in emergency department (ED) settings. Nineteen million new STD cases are diagnosed annually in the United States, for one of the highest rates of STDs in the industrialized world.

Because EDs often are used as a source of primary health care, the role of emergency departments in screening and treating STDs has been debated. A major area of difficulty with use of EDs for this purpose is that many test results are not available during the ED visit, and treatment decisions are therefore made presumptively. Errors are made in both overtreating and undertreating STDs in this setting. Although it has been shown that health care providers are significantly overtreating women who test negative for gonorrhea and chlamydial infection, one third of patients who test positive for STDs in the ED are not treated during the initial visit, and a majority of untreated patients do not return for subsequent treatment. As a result, providers must weigh the cost of overtreatment against the risk of untreated disease. Because these diseases pose a significant public health risk, it is recommended that patients be treated presumptively in the ED unless good follow-up for test results can be ensured. To help contain these diseases, many states allow expedited partner therapy, allowing physicians to prescribe treatment not only for the patients being treated but also for their partners. Information on expedited partner therapy and the states that allow it is available on the Centers for Disease Control and Prevention (CDC) website (www.cdc.gov).

Patients with STDs present with a variety of symptoms and signs that most commonly involve the genitalia but also can include abdominal pain, dermatologic conditions, and systemic illness. To prevent both complications and spread of these diseases, accurate and timely diagnosis and treatment are crucial.

As with many other illnesses, history and physical examination provide much of the clinical information needed to diagnose STDs. Patients should be questioned about current and previous symptoms and their duration, as well as any previous history of STDs, recent sexual contacts, use of contraceptives (particularly barrier devices such as condoms), and types of sexual practices; women should additionally be questioned about their menstrual history. Physical examination should focus on the symptomatic area, often the genitalia. Evidence of skin lesions and their type as well as presence of discharge should be noted. Examination of the skin and lymph nodes may be an important component of the examination, particularly in the case of syphilis or gonorrhea. Evidence of septic arthritis on examination of symptomatic joints may indicate gonococcal arthritis and disseminated gonococcal infection.

The STDs can be split into two categories: those that manifest with genital ulcers, with or without adenopathy, and those that are nonulcerative, which most frequently manifest with genital discharge (Table 96-1).

DISORDERS CHARACTERIZED BY GENITAL LESIONS WITH OR WITHOUT ADENOPATHY

STDs constitute a common and well-recognized cause of genital lesions. As a point of clinical importance, however, patients who present with a “sore” on or near the genitalia may be using this term to refer to genital warts, scabies, premalignant lesions, or other conditions. If an STD is the cause, certain components of the history and physical examination can provide crucial information to help narrow the diagnosis to a specific infection (Table 96-2). History and physical examination should focus on the characteristics of the lesion or lesions, the presence or absence of adenopathy, and the presence or absence of systemic symptoms. In regard to the lesions, it is important to determine whether they are single or multiple, painful or painless, indurated or soft; whether they have irregular or regular borders; and how they began (e.g., as a vesicle or papule). If the patient has lymphadenopathy, it should be noted whether the condition is unilateral or bilateral, and the involved area should be evaluated for the presence of fluctuance and pain.

In evaluating a patient with genital ulcerative lesions, herpes simplex virus (HSV) testing and syphilis serologic studies should be undertaken; if feasible, a darkfield examination of the lesion scrapings also is useful. In addition, patients should be referred for human immunodeficiency virus (HIV) testing, because ulcerative genital lesions increase the risk of acquiring HIV infection.

Comprehensive test results often are not available during the patient’s ED evaluation; therefore, treatment should be considered for the more likely diagnoses based on history and physical examination findings. The most common ulcerative diseases in the United States are herpes and syphilis; herpes occurs much more frequently than syphilis. In rare outbreaks, chancroid may be the cause of the ulceration.
HERPES

In the United States, genital herpes is the most common cause of ulcerative STDs, with 50 million people infected with the virus and 200,000 to 300,000 new symptomatic cases annually. One in five sexually active adults is infected with the virus. Most commonly caused by herpes simplex virus type 2 (HSV-2), genital herpes also can be caused by HSV-1. In pregnant patients, herpes can cause a devastating congenital infection, although the incidence of such infections has decreased. In addition, HSV infection plays a major role in the transmission of HIV, because herpetic lesions can increase the risk of both acquisition and transmission of HIV.

Clinically, genital herpes manifests as either primary herpes infection or recurrence. In primary infections, the degree of illness depends on whether the patient has preexisting circulating antibodies to either HSV-1 or HSV-2; those with antibodies tend to have a milder syndrome with initial genital infection than those without. With primary infection in patients without antibodies, symptoms develop after a 2- to 7-day incubation period. The syndrome begins with genital lesions that tend to be painful, shallow, multiple, and grouped (Fig. 96-1); in women, they may coalesce into large ulcerations on the perineum (Fig. 96-2). Systemic symptoms may include low-grade fever, myalgias, headache, and fatigue. Adenopathy typically develops during the second or third week of the illness and is bilateral, mildly tender, and nonfluctuant. The local symptoms peak at approximately 8 to 10 days, and it takes 2 to 4 weeks for the lesions to completely heal. Viral shedding can last as long as 3 weeks. In some cases, sacral

Figure 96-1. Genital herpes lesions on the penile shaft.
radiculopathy may develop, with urinary retention, constipation, and sensory changes in the perineal region. Aseptic meningitis and transverse myelitis are relatively uncommon complications. In patients with circulating antibodies to the herpesvirus, genital lesions alone usually characterize the initial infection.

As the symptoms of primary infection recede, the virus takes residence in the spinal cord ganglia and becomes latent, residing there for the lifetime of the patient. Symptomatic recurrences are the rule, occurring in 60 to 90% of patients. In contrast with the prolonged syndrome and systemic symptoms of primary infection, recurrences are much shorter in duration and tend to cause only mild local symptoms. Many patients will be warned of an impending recurrence by a prodrome, often characterized by paresthesias, burning, or itching at the site of the subsequent lesions. Although it is known that viral shedding can occur during a recurrence, data suggest that in patients infected with HSV-2, shedding occurs during asymptomatic periods as well.

Population screening with serologic tests for HSV-2 suggests that many people become infected with the virus without symptoms or knowledge of having acquired the infection. Patients with only serologic evidence for past infection may be a potential reservoir for transmission of the virus.

**Diagnosis**

Although the diagnosis of genital herpes usually is made clinically, this diagnostic strategy is both insensitive and nonspecific. Confirmatory testing should be strongly considered, particularly in women of childbearing age. Several methods are available, including viral culture and antigen testing methods of the lesions, as well as new type-specific viral serologic testing of the blood; a positive result on any of these tests is considered definitive. The Tzanck test, used in the past for diagnosis of herpes infection, is no longer recommended because of its lack of sensitivity.

Although viral culture of a lesion traditionally has been and still is considered to be the “gold standard” diagnostic modal-

---

**Treatment**

Although genital herpes is incurable and outbreaks are self-limited, treatment decreases the duration of symptoms in patients with primary infection, can shorten or abort recurrences, and decreases the amount and duration of viral shedding and therefore potential infectivity. In patients with frequent recurrences (six or more per year), suppressive therapy can decrease the number of these episodes by up to 80%.\(^8\) The mainstay of treatment is therapy with one of the antiviral drugs acyclovir, valacyclovir, and famciclovir\(^5\) (Table 96-3). None of these agents can eliminate the virus, but their use can control symptoms, at least while the drug is being taken. Acyclovir has been shown to be safe for up to 6 years’ continuous use as a suppressive agent; the other antivirals have been proved safe for 1 year.\(^3\)

Patient education is critical in cases of genital herpes. The importance of testing the patient’s sexual partner or partners should be emphasized, and the patient should be told that he or she can potentially transmit the virus and infect a sexual partner even during asymptomatic periods. If the patient is a woman of childbearing age, she must be instructed to inform her physician of her history of genital herpes if she becomes pregnant.

Neonatal herpes is a devastating and potentially fatal infection seen most often in women who acquire the infection during their pregnancy, whether or not the patient is symptomatic. Cesarean section is the preferred method of delivery if the patient has active lesions at the time of onset of labor. Because the antiviral agents used to treat genital herpes have not been proved safe during pregnancy, the decision to use these agents should be made in conjunction with both the patient and her physician.

**BARTHO LIN CYST AND ABSCESS**

The Bartholin glands are located inferiorly on either side of the vaginal opening. The glands normally secrete fluid through their openings on the sides of the vestibule. The ducts and glands are palpable or visible only when obstructed, infected, or inflamed. When the duct of the gland becomes obstructed, a simple cyst develops, which usually is painless. Patients with a Bartholin gland cyst typically report a lump at the lateral introitus, and on examination, an ovoid mass can be palpated on the mucosal surface of the lateral posterior introitus, just above the posterior fourchette. Treatment usually consists of incision and drainage using local anesthesia with Word catheter placement and sitz baths. Simple packing can be used, but the cavity may need repacking multiple times as the area heals.

A Bartholin abscess develops when a Bartholin cyst becomes secondarily infected. A majority of abscesses involve the

*Because of resistance, quinolones are no longer recommended for the treatment of gonorrhea.

anaerobic and aerobic bacteria normally found in the vagina. However, they also can be due to sexually transmitted infections, including infection with *Neisseria gonorrhoeae* and *Chlamydia trachomatis*. Other commonly implicated bacteria include *Bacteroides* species, *Escherichia coli*, and other gram-negative organisms. Patients with a Bartholin abscess present with swelling and pain at the lower lateral vaginal opening and may report a lump or mass near the affected labium. On examination, patients may have a swollen and painful labium, and a tender, fluctuant mass can be palpated on the posterolateral margin of the vaginal vestibule. Cellulitis may be present with surrounding edema and erythema.

Treatment options include incision and drainage, with the incision on the mucosal surface of the vestibule. Iodoform gauze can be used as a packing material to promote ongoing drainage, but it is preferable to use a Word catheter for this purpose. This small catheter is placed into the incision, and the balloon on the catheter is then inflated with 2 to 4 mL of water or saline. The catheter is left in place for 6 to 8 weeks until epithelialization along the catheter tract has occurred. Although this treatment is adequate in most patients, management of recurrent infections may require marsupialization, creating a permanent fistula that prevents recurrent abscess formation. Antibiotics usually are not necessary unless significant surrounding cellulitis is present. Patients are instructed to start sitz baths within 24 hours of ED discharge to promote drainage. Patients should be referred for follow-up for reexamination of the wound within 48 hours. Because some Bartholin abscesses are caused by sexually transmitted organisms, abscess drainage should be cultured and routine testing for STDs performed, and patients should be treated with appropriate antibiotic therapy to cover *Chlamydia* and *N. gonorrhoeae*.

SYPHILIS

Syphilis, also known as the “Great Imitator,” is caused by the spirochete *Treponema pallidum* and earns its nickname from its ability to infect any organ of the body and cause multiple symptoms.

The organism is fragile and does not survive on dry surfaces. Transmission occurs during exposure of moist skin to an infected area. Although transmission usually involves the genitalia, inoculation can occur virtually anywhere on the
The incidence of this infection hit a nadir in 2000; since then it has been increasing steadily, and now nearly 10,000 cases of primary and secondary syphilis are reported annually in the United States.\textsuperscript{5,12}

If untreated, syphilis typically progresses through several stages, as follows.

1. **Primary.** The primary lesion, called a \textit{chancre}, occurs after an incubation period that varies from 9 to 90 days, averaging 2 to 4 weeks. This lesion occurs at the site of inoculation and begins as a papule that then becomes ulcerative. Typically, the chancre is painless and single and has a smooth, slightly raised edge, with sharply defined borders and a clean base (Fig. 96-3); occasionally, patients present with more than one lesion (Fig. 96-4). Without treatment, the chancre lasts for 2 to 6 weeks and resolves spontaneously, and the disease progresses to the secondary stage. Adenopathy is not a predominant feature of primary syphilis. If the chancre is on the genitalia, bilateral, painless, nonfluctuant, and slightly enlarged inguinal adenopathy may develop several days after appearance of the primary chancre.

2. **Secondary.** At 5 to 8 weeks after resolution of signs and symptoms of primary syphilis, the patient begins to exhibit manifestations of the secondary stage of the disease. The most common manifestation is a total body rash (Fig. 96-5). This rash begins on the trunk as a fine macular rash, which then spreads outward to the arms and legs and may involve the palms and soles (Fig. 96-6). As it progresses, it becomes papulosquamous and may appear slightly annular, often resembling the rash of pityriasis rosea. Mucous patches can be seen on the tongue, which are the oral manifestations of the skin rash. Condylomata lata (Fig. 96-7) also can develop; these lesions are broad-based papules with flat moist tops, occurring in the perineal region, which may involve the anus, the skin between the buttocks, and the labia. Constitutional signs and symptoms are common during this stage, including fatigue, low-grade fever, malaise,
Figure 96-7. Condylomata lata of secondary syphilis.

Diagnosis

The only rapid means of diagnosing syphilis is the darkfield examination. This method involves viewing scrapings or fluid from lesions of primary or secondary syphilis under a darkfield microscope to identify the spirochete. Unfortunately, the sensitivity of darkfield microscopy is approximately 80%, and many hospitals and clinics do not have this technique routinely available.

Serologic testing is the current standard for diagnosing secondary, latent, and tertiary syphilis; for primary syphilis, one-time testing is less reliable, and follow-up testing may be necessary. The two types of serologic tests are nontreponemal—the Venereal Disease Research Laboratory (VDRL) and rapid plasma reagin (RPR) tests—and treponemal—(MHA-TP) and (FTA-ABS). Both tests are necessary for definitive diagnosis, although the nontreponemal test is used for screening, with treponemal testing used for confirmation. Nontreponemal tests measure nonspecific antibodies in serum from patients with syphilis, and the titers vary with the stage and activity of disease. These tests yield a positive result at approximately 2 weeks after the primary chancre appears and involve quantitative measurement of antibody. Titers are used to follow response to treatment. Because these tests are nonspecific for the treponeme and false-positive results can occur, positive test results should be confirmed with the more specific treponemal tests. Treponemal tests measure antibodies specific to the spirochete Treponema pallidum. These tests are more expensive and difficult to perform than the nontreponemal tests, and because their titers do not predictably vary with treatment, the main value of these tests is in confirming positive findings on nontreponemal tests.

Treatment

A one-time dose of the long-acting formulation of penicillin G benzathine, 2.4 million units IM, is the regimen of choice for treating primary and secondary syphilis (see Table 96-3 for treatment of latent and tertiary syphilis). It is crucial that the long-acting form of penicillin G benzathine be used; the halflife of an alternative preparation comprising both penicillin G benzathine and penicillin G procaine (i.e., Bicillin C-R) is too short, which has resulted in treatment failures. Sexual partners need to be evaluated; partners within the last 90 days should be tested but treated presumptively; and former partners from more than 90 days before diagnosis should be evaluated and treated if indicated. Because syphilis increases the risk of acquisition of HIV, all patients should be referred for HIV testing. To ensure response to treatment, patients should be reexamined clinically and serologically 6 and 12 months after treatment. Successful treatment is confirmed by either a nonreactive nontreponemal test or a fourfold or greater decrease in titers after 6 months. Because syphilis is a reportable disease, patients with positive test results should be reported to the public health department.

In the pregnant patient with syphilis, congenital syphilis with its devastating outcome is a significant concern. Parenteral penicillin G is the only agent with documented efficacy in these instances. In pregnant women with syphilis at any stage with a reported penicillin allergy, treatment with penicillin G procaine (i.e., Bicillin C-R) is too expensive and difficult to perform than the nontreponemal tests, and because their titers do not predictably vary with treatment, the main value of these tests is in confirming positive findings on nontreponemal tests.

LYMPHOGRANULOMA VENEREUM

Lymphogranuloma venereum is a chronic STD caused by specific serotypes of Chlamydia trachomatis. Although this disease is prevalent in many tropical countries, it is rare in the United States and is seen either in patients who have traveled to endemic areas or in localized outbreaks in patient populations such as men who have sex with men. The incubation period ranges from 3 days to 3 weeks. The initial infection manifests as a transient genital lesion that is small and painless and often goes unnoticed by the patient. The secondary stage, characterized by involvement of the lymphatic channels and nodes of the genitalia, pelvis, and rectum, begins at 7 to 30 days after the primary lesion disappears. The patient usually presents at this secondary stage, when regional lymphadenitis appears. Inguinal lymphadenopathy most often is unilateral, and enlargement of the glands above and below Poupart’s ligament gives the characteristic lymphogranuloma venereum “groove sign.” The enlarged nodes often are painful, with overlying erythema, but usually are not fluctuant. The nodes either eventually break down, with the formation of multiple draining sinuses, or form a hard inguinal mass without suppuration. The late complication of distal lymphedema results from the blockage of lymphatic channels.

Diagnosis

Diagnosis is based on the clinical picture, epidemiologic information, and the exclusion of other causes of inguinal lymphadenopathy and genital ulcers.
Treatment

Treatment is curative and prevents ongoing tissue damage. The preferred treatment is with doxycycline, 100 mg PO twice daily for 21 days; erythromycin base 500 mg PO four times daily for 21 days is an alternative regimen.\(^5\) Patients should refer their sexual partners for evaluation and treatment, and all patients should be referred for HIV testing.

\section*{CHANCROID}

Chancroid is caused by \textit{Haemophilus ducreyi}, a small gram-negative bacterium. This disease is common in developing countries\(^13\) but rare in the United States, with usually less than 100 cases reported annually to the Centers for Disease Control and Prevention (CDC).\(^3\) Despite its being relatively rare, outbreaks of chancroid have been reported in the United States, and physicians should be aware of the characteristics of this disease to permit recognition of these occasional outbreaks when they occur.

Clinically, chancroid is characterized by multiple painful genital ulcerations and inguinal bubo formation (Fig. 96-8). After an incubation period of less than 1 week, a short-lived, small, tender red papule appears at the site of inoculation. This lesion rapidly ulcerates, followed by the formation of multiple shallow, painful ulcers with sharply demarcated edges and purulent bases that last 1 to 2 weeks; in some patients, these lesions coalesce. Inguinal lymph node involvement is seen in 50\% of patients, manifesting 1 week after the ulcers appear. Typically, a unilateral large, painful, fluctuant lymph node (bubo) develops in the groin. Overlying skin is thinned and erythematous, and suppuration is common. These buboes can spontaneously rupture.

On a clinical basis, it may be difficult to distinguish chancroid from genital herpes. The presence of a large, fluctuant bubo strongly suggests chancroid. However, if only ulcers are present, the patient can have either disease. Because ulcers is several orders of magnitude more common in the United States than chancroid (which tends to occur in isolated outbreaks), herpes should be the first diagnosis considered.

\section*{Diagnosis}

\textit{H. ducreyi} is difficult to culture, so the diagnosis is based on clinical presentation and often is one of exclusion, after other diseases such as herpes and syphilis are ruled out by testing. Definitive diagnosis requires isolation and identification of \textit{H. ducreyi}, a fastidious organism requiring a special growth medium that is not routinely available. Because definitive diagnosis can be elusive, a “probable diagnosis” can be made if all of the following criteria are met: (1) The patient has one or more painful genital ulcers; (2) the patient has no evidence of \textit{T. pallidum} infection on darkfield examination or serologic testing; (3) the clinical presentation, appearance of genital ulcers, and regional lymphadenopathy are typical for chancroid; and (4) results of HSV testing performed on the ulcer exudates are negative.\(^3\) When local outbreaks are known, the microbiology laboratory can prepare the special medium required for growth of the organism to confirm specific cases, as well as to follow containment of the infection.

Any of the following four curative treatment regimens may be used: a single dose of azithromycin 1 g PO; a single dose of ceftriaxone 250 mg IM; ciprofloxacin 500 mg PO twice daily for 3 days; and erythromycin base 500 mg PO three times daily for 7 days (see Table 96-3 for additional treatment options).\(^5\) Co-infection with syphilis or HSV occurs in approximately 10\% of patients who have chancroid acquired in the United States. Chancroid is associated with increased HIV transmission, so all patients should be referred for HIV and other STD testing. Sexual partners of patients with chancroid should be examined and treated if sexual contact with the patient occurred during the 10 days preceding the patient’s onset of symptoms. To confirm response to treatment, patients should be re-examined at 3 to 7 days after initiation of therapy.

Drainage of buboes is not routinely recommended, because appropriate antibiotic treatment typically affects a good clinical response. If deemed necessary, needle aspiration of nodes in the supercilial aspect of the fluctuant area can be performed; re-aspiration usually is not necessary because the adenopathy responds quickly to antimicrobial treatment.

\section*{GRANULOMA INGUINALE}

Granuloma inguinale (donovanosis) is caused by \textit{Klebsiella granulomatis} (formerly known as \textit{Calymmatobacterium granulomatis}), an intracellular gram-negative rod. The disease is rare in developed countries but is endemic in tropical and semi-tropical regions, including India, Papua New Guinea, central Australia, and southern Africa. The disease is presumed to be sexually transmitted, with an incubation period of 8 to 80 days.

Clinically, the disease manifests as chronic, painless, progressive ulcerative lesions. The lesions are irregular, clean-based granulomatus ulcers that are highly vascular (giving the classic “beefy red appearance”) and bleed easily on contact. The ulcer feels hard when palpated. Regional lymphadenopathy does not occur. As the lesion enlarges, it can be quite mutilating to the genitalia, causing urethral stenosis over a period of months to years. Without adequate treatment, it may result in lymphatic obstruction, producing genital edema and eventually lower extremity elephantiasis. In men, the sites of predilection are the prepuce, the coronal sulcus, and the frenulum. In women, lesions typically are found on the labia, but vaginal and cervical lesions also can occur.

Diagnosis is difficult and requires identification of the infectious agent, which appears as short, pleomorphic rods with bipolar staining. Donovan bodies may be seen within histiocytes on microscopy of tissue crush preparation or biopsy specimen. The causative organism is very difficult to culture, so visualization of the organism with appropriate staining is the primary means of diagnosing the disease.

Treatment halts progression of the lesions, but relapse can occur 6 to 18 months after apparently successful treatment. The CDC-recommended regimen is doxycycline 100 mg PO twice daily for at least 3 weeks or until the lesions have healed.

\begin{figure}[h]
\centering
\includegraphics[width=\textwidth]{Figure_96-8.png}
\caption{Figure 96-8. Ulcerative lesions of the penis from chancroid with accompanying fluctuant, tender, erythematous lymphadenitis (bubo).}
\end{figure}
Anogenital warts are caused by the human papillomavirus (HPV), and more than 30 types of HPV can infect the genital tract. HPV infections most often are sexually transmitted, and lesions are most common at the site of greatest trauma during sexual intercourse. Most cases of HPV infection are asymptomatic or subclinical, with only approximately 1% resulting in clinically apparent warts. Most visible genital warts are caused by HPV types 6 and 11 and are benign. Other HPV types have been associated with external genital squamous intraepithelial neoplasia, however, as well as with vaginal, anal, and cervical intraepithelial dysplasia and squamous cell carcinoma.

Warts may be single or multiple (Fig. 96-9). Warts on warm, moist, nonhairy skin tend to be soft and nonkeratinized, whereas those on dry, hairy skin are more firm and keratinized. The lesions can be broad-based, pedunculated, or pigmented. Depending on the size and location, warts can be painful, friable, or pruritic. Warts that are indurated, fixed, ulcerated, or darkly pigmented may require biopsy to rule out carcinoma.

Diagnosis usually is made clinically. In women, a speculum examination is indicated to evaluate the patient for intravaginal and cervical lesions. Occasionally, HPV infections may be confused with the condylomata lata of syphilis. If any doubt about the diagnosis remains, or if warts have high-risk characteristics, biopsy and darkfield microscopy of tissue are indicated, along with serologic testing for syphilis.

Treatment is aimed at removal of symptomatic warts, including those that cause obstructive symptoms of the urethral meatus or rectum. Although wart-free periods may be obtained, treatment has not been shown to affect the course of disease or to reduce infectivity. If left untreated, visible genital warts may resolve spontaneously, remain unchanged, or increase in number.

Many treatment options are available, although no specific treatment has been proved to be superior to another; all have significant failure and recurrence rates. For patient-applied regimens, the patient must be able to identify and reach the warts to be treated with these methods. Provider-administered regimens often require ongoing treatments on a weekly basis and usually are best administered by a primary care physician, who can monitor the patient’s response to therapy. In general, warts located on moist surfaces respond better to topical treatments than do the keratinized warts found on drier surfaces. Patients should be instructed to watch for recurrences, which are most common in the first 3 months after treatment.

Patient preference, available resources, and physician experience should guide treatment. Most of these treatments are administered by the patient’s primary care physician and not through the ED. Treatment regimens can be divided into patient-applied and provider-administered.

**Patient-applied** regimens include the following:

- Podofilox 0.5% solution or gel, applied twice a day for 3 days, followed by 4 days of no therapy—which may be repeated, as necessary, for up to four cycles.
- Imiquimod 5% cream, applied once daily at bedtime, three times a week for up to 16 weeks. The treatment area should be washed with soap and water 6 to 10 hours after application.

**Provider-administered** regimens include the following:

- Cryotherapy with liquid nitrogen or cryoprobe, which may need to be repeated every 1 to 2 weeks
- Podophyllin resin, 10 to 25%
- Trichloroacetic acid or dichloroacetic acid, 80 to 90%
- Surgical removal

Podophyllin and podophyllum resin should be avoided in pregnant patients because of possible teratogenic effects. Imiquimod also is not approved for use during pregnancy. Immunosuppressed patients are more likely to demonstrate a poor response to treatment, increased relapse rates, and dysplasia and need close follow-up. All patients need screening for other sexually transmitted infections. Treatment of partners is not necessary.

In 2006, the U.S. Food and Drug Administration (FDA) licensed the human papillomavirus vaccine for use in girls and women aged 9 to 26 years. The vaccine covers the four virus types that are responsible for 70% of cases of cervical cancer and 90% of anogenital warts, and it is virtually 100% effective. Full vaccination involves a series of three injections over a 6-month period.

**DISORDERS CHARACTERIZED BY GENITAL DISCHARGE**

Patients with diseases that fall into the group of disorders characterized by genital discharge tend to present with ure-
chlamydial infection, gonorrhea, nongonococcal urethritis, trichomoniasis, bacterial vaginosis, candidiasis, and pelvic inflammatory disease (PID). Bacterial vaginosis and candidiasis are not sexually transmitted conditions but often are diagnosed in patients undergoing evaluation for STDs. Chlamydial infection and gonorrhea, the two most common nonulcerative STDs, also can cause vaginal discharge, especially in the setting of mucopurulent cervicitis, and both tend to cause urethral discharge in men. These two infections commonly occur concurrently, and clinical manifestations of these two infections are similar. It usually is not possible to distinguish between the two diseases on the basis of signs and symptoms alone, and patients often are appropriately treated presumptively for both infections (see Table 96-1).

### CHLAMYDIAL INFECTION

In the United States, chlamydial infection is diagnosed in just over 1 million people annually, and estimates are for nearly 3 million cases each year, making it the most commonly reported STD. The causative organism is *C. trachomatis*, an obligate intracellular organism that infects columnar and pseudostratified columnar epithelial surfaces. Infection with *C. trachomatis* can cause a variety of symptoms, including urethritis, cervicitis, epididymitis, proctitis, prostatitis, PID, and perihepatitis, also known as Fitz-Hugh–Curtis syndrome.

Symptoms appear after an incubation period of 1 to 3 weeks. Although urethritis is the most common manifestation in men, men also can present with epididymitis or both in combination. When symptomatic, women may report symptoms and signs ranging from dysuria to systemic illness related to periadenitis. Often, however, the presenting manifestations in women are vague and nonspecific: vaginal discharge or bleeding or abdominal or pelvic pain, or some combination thereof. Unfortunately, infection commonly is asymptomatic; estimates show that up to 75% of infected women and 50% of infected men have no symptoms. The highest rate of infection is in sexually active adolescent females, with infection rates as high as 10% in this group. Of note, PID, with its increased risk of subsequent ectopic pregnancy and infertility, develops in up to 40% of women with untreated chlamydial infection. Because of the high rate of asymptomatic infection and the increased risk for developing PID and its sequelae after chlamydial infection, screening of high-risk patients (those with multiple sexual partners) for disease may be appropriate in the ED so long as adequate follow-up is ensured. The CDC recommends *Chlamydia* testing for all women 25 years of age or younger and older women with risk factors (a new sexual partner or multiple sexual partners) and in all pregnant patients.

Until recently, the “gold standard” modality for diagnosing chlamydial infection was cell culture. Unfortunately, this test is labor-intensive, is fraught with difficulties, and takes days for definitive results. Although other nonculture techniques (DNA probe and latex agglutination testing) have been used since the 1990s to make the diagnosis of chlamydial infection, the more recently available tests based on nucleic acid amplification techniques have better sensitivity and specificity than culture and are rapidly becoming the new diagnostic method of choice. These nucleic acid amplification tests (NAATs) include ligase chain reaction, polymerase chain reaction (PCR), strand displacement amplification, and transcript-mediated amplification techniques. All of these techniques amplify nucleic acid sequences specific to the organism being tested and do not require viable organisms. NAATs have sensitivity rates better than that for culture (greater than 90%, versus 60 to 80%), with specificity greater than 99%. These new NAATs are more sensitive than other nonculture tests (DNA probe testing, latex agglutination testing) by 17 to 35%. NAATs can be performed on swabs (endocervical or urethral) and urine. Sensitivity of NAATs is lower when performed on urine than on endocervical swabs, so endocervical swabs constitute the sample of choice in females. Urine screening using NAATs is adequate for symptomatic male patients, and urethral swabs generally are not necessary. In sexual abuse cases, culture should still be performed in addition to the NAAT for medicolegal purposes.

Treatment of chlamydial infection consists of azithromycin 1 g PO in a single dose or doxycycline 100 mg PO twice daily for 7 days; alternative regimens are shown in Table 96-3. Co-infection with gonorrhea is common, so unless gonorrhea is definitively ruled out, patients should be treated for both infections. Patients should be instructed to abstain from sexual intercourse for 7 days after completion of treatment (either single-dose therapy or the 7-day regimen of doxycycline). Sexual partners need to be tested and treated, and the index patient also should be instructed to abstain from sexual intercourse until all partners are treated. Follow-up testing for cure is not required unless symptoms persist or reinfection is suspected.

### NONGONOCOCCAL URETHRITIS

Nongonococcal urethritis is characterized by urethral discharge, dysuria, or urethral pruritus and, although most commonly diagnosed in men, also can be seen in women. Although *C. trachomatis* is implicated in many cases, other organisms such as *Mycoplasma* and *Ureaplasma* also may be etiologic agents. All patients with suggestive presenting symptoms should be evaluated for both gonorrhea and chlamydial infection. The diagnosis is made by Gram’s stain (more than 5 white blood cells [WBCs] per high-power field and no gram-negative diplococci), a positive result on the leukocyte esterase test on urinalysis, or more than 10 WBCs per high-power field on urinalysis. Treatment consists of azithromycin 1 g PO in a single dose or doxycycline 100 mg PO twice daily for 7 days. In women, other causes of vaginal discharge must be ruled out, including chlamydial infection, trichomoniasis, and candidiasis. Patients with persistent symptoms despite adequate initial therapy (appropriate regimen and completion of treatment course) should be reevaluated for the accuracy of diagnosis. If the diagnosis was accurate, the patient should be treated with metronidazole 2 g in a single dose or tinidazole 2 g in a single dose; azithromycin 1 g as a single dose can be added if it was not used in the first treatment regimen.

### GONORRHEA

Gonorrhea is the second most frequently reported STD after chlamydial infection, with an estimated 600,000 new *N. gonorrhoeae* infections in the United States each year. Because infection involves columnar or transitional epithelium, this organism affects the urethra, rectum, cervical canal, pharynx, upper female genital tract, and conjunctival sac.

The most common clinical presentation in men is acute urethritis, characterized by dysuria and a penile discharge (Fig. 96-10), starting within 1 to 14 days of exposure. On examination, findings may include urethral meatal erythema and a purulent urethral discharge. Patients may present with epididymitis, although this is uncommon.
In women, primary infections often are asymptomatic or produce only vague symptoms such as vaginal discharge, abnormal vaginal bleeding, abdominal or pelvic pain, dyspareunia or dysuria, and frequency. Patients may not present until after the emergence of complications such as PID, which develops in up to 20% of women with untreated gonorrhea. Like chlamydial infection, symptomatic and asymptomatic gonococcal infection can cause PID with consequent tubal scarring that may lead to infertility or ectopic pregnancy.

Gonorrhea also can involve the oropharynx and the anorectal area. Gonococcal infection of the pharynx often is asymptomatic, but in symptomatic cases, patients present with sore throat and exudative tonsillitis. Most cases are self-limited. Anorectal involvement is more common in persons who engage in receptive anal intercourse but can occur in women from contamination from cervicovaginal secretions. Like pharyngeal infection, it often is asymptomatic. When it is symptomatic, patients complain of rectal discomfort or pain, tenesmus, constipation, dyspareunia, pruritus ani, and purulent or mucoid anal discharge or bleeding. Anoscopy reveals friable mucosa and mucopurulent exudate.

Gonococcal conjunctivitis can be a sight-threatening infection, so recognition of this form of infection is crucial. This infection can occur in newborns, in whom it is acquired during passage through an infected birth canal, and in adults, who often acquire the infection by direct inoculation from organisms on the fingers and then rubbed onto the eye. Symptomatic conjunctivitis is characterized by beefy red conjunctiva, chemosis, and purulent eye discharge that is copious. If untreated, it can progress to corneal ulceration or, in severe cases, gonococcal endophthalmitis and globe perforation.

Disseminated gonococcal infection (DGI) results from gonococcal bacteremia and occurs more frequently in women than in men. Typically, it manifests as the arthritis-dermatitis syndrome, characterized by a combination of any or all of the following: fevers, chills, monoarticular or oligoarticular arthritis or arthralgias, rash, and tenosynovitis. The rash of DGI consists of pustular acral skin lesions, usually found peripherally on the extremities. The lesions are described as necrotic pustules on an erythematous base and are tender to palpation. These lesions represent the consequence of septic emboli to small blood vessels during bacteremia. Joint involvement, the second most common manifestation of DGI, manifests with an acute monoarticular or oligoarticular septic arthritis. The knees are most commonly involved, followed by elbows, ankles, wrists, and small joints of the hands and feet. The involved joint is erythematous, is warm, often has an effusion, and is painful on range-of-motion testing. Other manifestations of DGI, although very rare, include hepatitis, myocarditis, endocarditis, and meningitis.

Definitive diagnosis of DGI is confirmed by isolating gonococci from the blood, synovial fluid, or infected skin; unfortunately, such isolation has relatively poor sensitivity. Presumptive diagnosis of DGI is based on the appropriate clinical presentation, plus isolation of gonococci from a source site.

## Diagnosis

Diagnostic tests for gonorrhea include Gram’s staining, culture, and NAATs. Gram’s staining is most useful in symptomatic men with urethritis or in patients with gonococcal conjunctivitis. In these cases, it is an excellent diagnostic test, with a sensitivity and specificity approaching 100%, and results are available rapidly. This test is much less useful in asymptomatic men and all women, owing to its decreased sensitivity in these groups.

Culture for *N. gonorrhoeae* is considered the “gold standard” method of diagnosis. Because this test can be used to isolate the organism for antimicrobial testing and determination of antibiotic sensitivities, it is useful in areas of rapidly emerging resistance. However, the utility of this test may be limited by improper specimen collection and handling. To maximize the yield of gonococcal culture, inoculating the specimen immediately after collection directly onto the appropriate medium optimizes viability of the organisms. If the specimen is from a sterile site, such as cerebrospinal fluid or synovial fluid, a non-selective medium such as chocolate agar is best. Specimens from nonsterile sites such as the cervix, urethra, rectum, or oropharynx, where normal bacterial flora is present, should be inoculated on selective media such as Martin-Lewis agar. If not transported immediately to the laboratory, specimens should be incubated at 35°C to 36.5°C in a carbon dioxide–enriched atmosphere after collection and transported to the laboratory in a carbon dioxide–enriched atmosphere.

The NAATs have good sensitivity and excellent specificity for detection of gonorrhea from endocervical, urethral, and urine samples. These tests are approved by the FDA for the detection of *C. trachomatis* and *N. gonorrhoeae* in endocervical swabs from women, urethral swabs from men, and urine from both men and women. Although sensitivities of NAATs are comparable with culture (95 to 99%), selected NAATs may be less sensitive when performed on urine than when performed on endocervical specimens or male urethral swabs. Therefore, in symptomatic patients, NAATs of endocervical swabs from women or urethral swabs from men are good alternatives to gonococcal culture, particularly when appropriate techniques for maximizing organism viability and culture cannot be achieved.

Although NAATs are useful for diagnosing cervical and urethral gonorrhea, culture is required for diagnosing organisms from sites such as the oropharynx, synovial fluid, anorectal area, and cerebrospinal fluid. In addition, culture is the diagnostic method of choice when the results will be used as evidence in legal investigations or to determine sensitivity to specific antibiotics.
TRICHRONIASIS

Trichomoniasis is caused by *Trichomonas vaginalis*, a flagellated protozoan. It is the most common nonviral STD in the world. As with other vaginal infections, up to 50% of infected women are asymptomatic. The most common presenting signs and symptoms include dysuria, vulvar irritation or itching, and vaginal discharge, often described as thin, malodorous, and yellow-green (Table 96-4). Affected patients also may report lower abdominal pain or discomfort and dyspareunia. Males are frequently asymptomatic and most often present as partners of infected women. *Trichomonas* has been implicated as a cause of nongonococcal urethritis in men, possibly responsible for up to 20% of cases. Rarely, men report purulent urethral discharge or symptoms consistent with prostatitis or epididymitis.

On physical examination, vaginal discharge is noted in up to 70% of patients, ranging in character from thin and scanty to the classic description of thick, frothy, and yellow. Vaginal pH is above 4.5. Punctate mucosal hemorrhages of the cervix (“strawberry cervix”) has been described in 2 to 10% of patients. However, the history and physical examination findings are not sensitive or specific enough to make the diagnosis on clinical grounds alone, and testing is indicated.

The diagnosis most often is made by microscopic examination of a wet mount slide, but this method has a sensitivity of only 60 to 70%; sensitivity varies with the skill and thoroughness of the examiner and is optimized by examination of the slide soon after specimen collection. Culture is more sensitive than wet mount techniques but is not widely performed, and culture results are not available in a timely manner for ED diagnosis and treatment. In men, urine sediment can be examined for trichomonads and also can be sent for culture. PCR assay is an alternate method for diagnosis of trichomoniasis. Several PCR primers have been studied, and each has demonstrated higher sensitivity than wet mount or culture. PCR assay also has been found to be highly specific, exceeding 95%. In addition, PCR analysis of specimens obtained from the distal vagina had a higher sensitivity and specificity for diagnosis of trichomoniasis than wet mount or culture of specimens obtained during a speculum examination, suggesting a role for less invasive diagnostic sampling such as use of vaginal introitus swabs. PCR testing is now available for combined point-of-care testing for *Trichomonas* along with *Gardnerella vaginalis* and *C. albicans*.

Either of two single-dose treatments is recommended: metronidazole 2 g PO or tinidazole 2 g PO. Alternative therapy is metronidazole 500 mg PO twice daily for 7 days (see Table 96-4). Because these nitroimidazoles can cause a disulfiram-type reaction in persons who subsequently consume alcohol, patients taking these agents should be advised to avoid imbiring for 24 or 72 hours after the last dose of metronidazole or tinidazole, respectively. Topical metronidazole is available but is less efficacious than oral preparations for treatment of trichomoniasis and is not recommended for this use.

Trichomoniasis has been associated with premature rupture of membranes, premature labor, low birth weight, and posthysterectomy infection. Symptomatic pregnant women should be treated with metronidazole, 500 mg PO bid for 7 days. Metronidazole does not appear to be associated with an increased teratogenic risk during pregnancy. Its role in treatment of asymptomatic pregnant women infected with *Trichomonas* is less clear, and routine screening and treatment of asymptomatic women are not recommended.

Sexual partners of patients with *T. vaginalis* should be treated, and patients should be instructed to avoid sexual contact until they and their partners are clinically cured.

### CANDIDIASIS

Vulvovaginal candidiasis most often is caused by *Candida albicans* but can be caused by other *Candida* species and other yeasts. It is estimated that 75% of women will have at least one episode of yeast vulvovaginitis in their lifetime, and 40 to 45% will have two or more episodes. Common presenting signs and symptoms include vulvar itching or soreness, vaginal discharge, dyspareunia, and dysuria. Characteristic examination findings are vulvar erythema, vulvar edema or excoriation, and raised, white adherent vaginal plaques. Satellite lesions also may be seen. Vaginal pH is

normal (less than 4.5) (see Table 96-4). Because none of these symptoms or signs is specific for candidiasis and the history and examination findings are relatively unreliable, diagnostic testing is indicated.

Diagnosis typically is based on wet-mount microscopy using potassium hydroxide (KOH) preparation or Gram’s stain demonstrating yeast or pseudohyphae. The sensitivity of these tests ranges from 40 to 70%. Culture is considered the “gold standard” diagnostic modality but is rarely performed, and 10 to 20% of asymptomatic women harbor Candida organisms and other yeasts in the vagina. Latex agglutination tests also are available for point-of-care testing and may offer benefit over microscopy.

Multiple short-course topical preparations are available for treatment and effect an 80 to 95% cure rate in patients who complete therapy (see Table 96-4 for recommended regimens), and many are available over the counter. Self-medication with over-the-counter preparations should be advised only for women who have been diagnosed previously with vulvovaginal candidiasis and experience recurrence of the same symptoms. Unnecessary or inappropriate use of over-the-counter preparations is common, can lead to contact or irritant vulvar dermatitis, and may delay treatment for other causes of vulvovaginitis. In addition, patients should be counseled that vaginal preparations are oil-based, which may weaken latex condoms and diaphragms. Fluconazole, 150 mg in a single dose, is the only oral agent that is approved by the FDA for the treatment of candidiasis.

Candidal infections can be divided into complicated and uncomplicated types. Uncomplicated vaginitis is seen in 90% of patients. It is characterized by sporadic or infrequent episodes with mild to moderate symptoms due to C. albicans in a normal host. It responds readily to short-course treatments. Complicated infections, associated with severe or recurrent symptoms (four or more episodes of vulvovaginal candidiasis each year), tend to occur in patients with complicating medical problems (e.g., immunosuppression, poorly controlled diabetes mellitus) and require longer courses of treatment (e.g., 7 to 14 days of topical therapy or a 150-mg oral dose of fluconazole given in three doses on days 1, 4, and 7).25,34 Vulvovaginal candidiasis in HIV-positive patients is not considered complicated and should be treated as for uncomplicated vulvovaginal candidiasis.

Vulvovaginal candidiasis occurs frequently during pregnancy and may be more difficult to cure. Only topical azole therapies, applied for 7 days, are recommended for use during pregnancy; fluconazole is contraindicated.

Evidence to support treatment of asymptomatic sexual partners is lacking. In addition, no direct association has been found between yeast infection and other STDs, and no differential diagnosis finds has been observed in patients who have an STD and in those who do not.

**Bacterial Vaginosis**

Bacterial vaginosis occurs owing to a shift in bacterial flora in the vagina, with replacement of the normal H2O2-producing *Lactobacillus* species with high concentrations of a polymicrobial group, including anaerobic bacteria (*Prevotella*, *Mobiluncus*, and *Bacteroides* species), *G. vaginalis*, and *Mycoplasma hominis*, and an attendant increase in the vaginal pH from 4.5 to as high as 7.0. Bacterial vaginosis is the most common cause of vaginal discharge and malodor (see Table 96-4). However, up to 50% of women with bacterial vaginosis are asymptomatic.

The most common manifestation is vaginal discharge, often with an offensive vaginal odor, which may be accentuated after coitus (the alkaline pH of semen induces a fishy odor, recognition of which constitutes a physiologic “whiff test”). Vaginal pruritus and irritation are not common complaints. On examination, a thin, white, homogeneous discharge is present.

Diagnosis can be made using the Amsel criteria (see Table 96-4). Three of the four criteria must be present for diagnosis:

1. A thin, white homogeneous discharge.
2. Presence of clue cells in microscopic examination. True clue cells are epithelial cells that are so heavily stippled with bacteria that the cell borders are obscured. Epithelial cells with few bacteria do not classify as clue cells.
3. pH of vaginal fluid greater than 4.5.
4. A fishy odor to the vaginal discharge before or after the addition of 10% KOH (“whiff test”).

Diagnosis also can be made with Gram’s staining to determine the relative concentrations of bacterial morphotypes (Nugent criteria). Culture isolation of *G. vaginalis* is not useful, because this organism can be cultured from vaginal specimens in more than 50% of healthy women and is therefore not specific. Other diagnostic modalities include a DNA probe–based test (Affirm VP III) and card tests, which detect elevated pH as well as the presence of elevated amine concentration (FemExam test) or proline aminopeptidase (Pip Activity Test Card). The card tests indicate the presence of two of the four criteria recommended for diagnosis by the CDC, so correlation of results with microscopy or appropriate examination findings is necessary; such tests are not used in isolation to make the diagnosis.

All women who have symptomatic disease require treatment. Bacterial vaginosis is associated with an increased risk of acute upper genital tract infection by the various organisms recognized as likely pathogens in such infections. It is not known whether treatment of bacterial vaginosis reduces the risk of ascending infection, so screening for and treatment of bacterial vaginosis in asymptomatic women are not recommended at this time. Bacterial vaginosis also has been associated with endometritis and PID and with vaginal cuff cellulositis after invasive procedures, including endometrial biopsy, hysterectomy, and placement of an intrauterine device. The latter association suggests some role for prophylactic metronidazole in certain patients. Recommended treatment regimens for bacterial vaginosis include metronidazole 500 mg PO twice a day for 7 days, metronidazole gel 0.75% 5 g intravaginally every day for 5 days, and clindamycin cream 2%, 5 g intravaginally at bedtime for 7 days. The vaginal cream may be less efficacious than oral metronidazole. Alternative regimens include clindamycin 300 mg PO twice a day for 7 days and clindamycin ointed 100 mg administered intravaginally once at bedtime for 3 days. Of note, alternative regimens have lower efficacy for treatment of bacterial vaginosis. Patients should be advised to avoid alcohol for up to several days after treatment with metronidazole. Treatment of sexual partners does not affect response to therapy or recurrence rates in clinical trials and is therefore not recommended.

Bacterial vaginosis during pregnancy is associated with premature rupture of membranes and preterm labor, preterm birth, and postpartum endometritis. Studies have not demonstrated a benefit of treatment for asymptomatic pregnant patients; however, in women with a previous preterm birth or those who are at high risk for preterm birth, treatment with metronidazole has been shown to reduce the risk of spontaneous preterm birth. Treatment of asymptomatic bacterial vaginosis in pregnant women does not reduce the occurrence of preterm delivery. Recommended treatment regimens in
pregnancy include metronidazole 500 mg orally twice a day for 7 days, metronidazole 250 mg PO three times a day for 7 days, and clindamycin 300 mg PO twice a day for 7 days. Topical agents are not recommended for use during pregnancy. Metronidazole use during pregnancy has no demonstrated association with teratogenic or mutagenic effects in newborns.

### OTHER CAUSES OF GENITAL DISCOMFORT

Many other conditions manifest with vulvovaginal itching or discharge. Considerations in the differential diagnosis include the sexually transmitted and vaginal infections discussed previously, as well as allergic or chemical vaginitis, atrophic vaginitis, scabies, pediculosis pubis (genital lice), and vaginal foreign bodies.

Chemical vaginitis most commonly is associated with the use of douches, scented soaps, or feminine hygiene products. In addition, some women with a latex allergy may present with vaginal itching and discomfort after intercourse with a partner who uses latex condoms. Diagnosis is by history, and discontinuing use of the offending agent usually is sufficient treatment.

Atrophic vaginitis occurs when levels of circulating estrogens decrease after menopause. Patients may report increased vaginal itching, vulvar discomfort, and dyspareunia. Other sources of discomfort, such as *Candida* infection, must be ruled out, because relative lack of estrogen predisposes affected women to vaginal and vulvar infections. Treatment typically consists of topical estrogen creams.

The mite *Sarcoptes scabiei* causes scabies infestation, and any part of the body may be affected. Transmission is by skin contact. The main symptom is pruritus, which is caused by a hypersensitivity reaction to mite excrement. The diagnosis is made clinically by identification of characteristic silvery lines seen in the skin where the mites have burrowed. Papules or nodules also may be noted, especially in the genital area. Scrapings viewed under the light microscope contain mites, confirming the diagnosis. The CDC-recommended treatment is permethrin 5% cream, applied to the whole body from the neck down and washed off after 8 hours; or ivermectin, 200 µg/kg orally, repeated in 2 weeks. Treatment should be repeated in 1 week. An alternative regimen is lindane 1%, 1 ounce of lotion or 30 g of cream applied in a thin layer to all areas of the body from the neck down and washed off after 8 hours. Lindane should not be used on infants or during pregnancy. Antihistamines and topical creams may give symptomatic relief. Potentially contaminated clothes and bedding should be washed at high temperature or not used for 72 hours (mites die when separated from the human host for 72 hours). Sexual and household contacts should be treated.

*Phthirus pubis* is a crab louse transmitted by close body contact. Adult lice infest pubic hair, body hair, and occasionally the eyebrows and eyelashes. Eggs (nits) adhere to the hairs. The main symptom is pruritus due to hypersensitivity reaction to the feeding lice. Diagnosis is based on finding adult lice or eggs. A number of treatments are available. Lotions probably are more effective than shampoos and should be applied to all body hair. The primary CDC-recommended treatment is permethrin 1% cream rinse applied to affected areas and washed off after 10 minutes. Alternative regimens are malathion 0.5% lotion, applied for 8 to 12 hours and then washed off, and ivermectin 200 µg/kg orally, repeated in 2 weeks. Sexual partners should be treated, and patients should be screened for other STDS. Potentially contaminated clothes and bedding should be washed at high temperature.

### PELVIC INFLAMMATORY DISEASE

#### Perspective

PID comprises a spectrum of disorders of the female upper genital tract, including any combination of endometritis, salpingitis, peritonitis, and tubo-ovarian abscess. Approximately 750,000 cases of PID are diagnosed annually in the United States. The serious complications of PID (infertility, ectopic pregnancy, and chronic pelvic pain) account for a significant proportion of non-HIV STD-related morbidity in the United States and afflict approximately 25% of diagnosed patients. PID is reported to be the most common serious infection in women of reproductive age and causes approximately 30% of infertility cases, 50% of ectopic pregnancies, and many cases of chronic pelvic pain.

#### Principles of Disease

PID is an ascending infection, with the infecting microorganisms spreading from the cervix and vagina to the upper portions of the female genital tract. Although the most commonly implicated organisms are *C. trachomatis* and *N. gonorrhoeae*, the cause of PID often is polymicrobial, and various microorganisms have been recovered in patients with acute PID, including genital mycoplasmas and anaerobic and aerobic bacteria from endogenous vaginal flora such as *Prevotella* species, *Peptostreptococcus*, *G. vaginalis*, *E. coli*, *H. influenzae*, and aerobic streptococci. Although organisms that are associated with sexual transmission are those most commonly found with PID, this infection can be caused by nonsexually acquired organisms. Patients diagnosed with PID should be counseled that the infection can be acquired nonsexually and that the diagnosis does not imply that either sexual partner may have had sexual encounters outside the relationship.

Risk factors for the development of PID include young age, multiple sexual partners, cigarette smoking, and menses. Intrauterine contraceptive devices (IUDs) have previously been implicated as a major risk factor for PID; however, IUDs increase the risk of PID only in the first month after insertion. It should be noted that nearly half of patients with PID do not have identifiable risk factors; a lack of risk factors does not rule out the infection.

#### Clinical Features

Owing to the wide variety of presenting signs and symptoms, acute PID is challenging to diagnose. The most common presenting symptom is lower abdominal pain. Other common signs and symptoms include dyspareunia, abnormal bleeding, and abnormal cervical or vaginal discharge. Physical examination may reveal lower abdominal tenderness, cervical motion or adnexal tenderness (unilateral or bilateral) on bimanual palpation, and fever with temperatures higher than 38°C.

Studies show that many women with PID demonstrate mild, vague, or subtle symptoms, often not recognized as manifestations of PID. Unrecognized PID probably is as common as, if not more common than, clinically apparent disease, and it is estimated that up to two thirds of cases go unrecognized. *Silent* or *atypical* PID is a term that has been used to describe the underlying disorder in women with documented tubal infertility who have no history of being diagnosed with PID despite confirmed chronic inflammatory residua. Unrecognized or atypical PID usually is characterized by abdominal pain, abnormal uterine bleeding, and mucopurulent endocervical discharge; fever may not be present in these patients.

Patients also can present with right upper quadrant pain and tenderness, which may be preceded or accompanied by the
signs and symptoms of PID. This syndrome, known as perihepatitis or Fitz-Hugh–Curtis syndrome, has been associated with both gonococcal and chlamydial salpingitis. Transaminases and gallbladder ultrasound findings will be normal. Fitz-Hugh–Curtis syndrome may develop in up to 10% of patients with PID, depending on the organisms implicated as the cause.42

Unfortunately, the clinical examination has low sensitivity for the diagnosis of PID. One study comparing clinical diagnosis with laparoscopic findings showed that the clinical diagnosis of PID is no more accurate than chance when compared with biopsy-confirmed diagnosis.43,44 Laparoscopic studies support these findings, with sensitivity rates for clinical examination ranging from 50% to 75%.41,44 No single historical, physical, or laboratory finding is adequately sensitive or specific to permit a definitive diagnosis of PID. Because of the difficulty in making the diagnosis and the serious long-term sequelae of PID, current recommendations call for increased readiness to consider this clinical entity and to institute appropriate treatment in patients with suspected PID.

The CDC recommends empirical treatment for PID in sexually active young women experiencing pelvic or lower abdominal pain if any one of the following minimum criteria is present without other identifiable causes:

- Cervical motion tenderness or
- Adnexal tenderness or
- Uterine tenderness

Controversy also surrounds what constitutes cervical motion tenderness. Although the traditional “chandelier sign” (pain so severe the patient ends up swinging from a chandelier) of severe tenderness has been taught as the criterion standard, studies indicate that the patient herself should be questioned about her degree of pain. If it is more than the usual discomfort experienced by the patient during a pelvic examination, this should be considered positive evidence for cervical motion tenderness.

Other criteria that support but are not necessary for the diagnosis of PID include the following:

- Oral temperature greater than 101°F (38.3°C)
- Abnormal cervical or vaginal mucopurulent discharge
- Presence of WBCs on wet mount preparations of vaginal secretions
- Elevated erythrocyte sedimentation rate
- Elevated C-reactive protein level
- Laboratory documentation of cervical infection with N. gonorrhoeae or Chlamydia

When more criteria for diagnosis are met, the specificity increases but the sensitivity decreases. The absence of WBCs on wet mount preparations makes the diagnosis of PID unlikely; in such cases, other causes of abdominal pain should be sought. Ultrasonography also may be useful in the diagnosis of PID, especially in identifying tubo-ovarian abscess or pyosalpinx. If the diagnosis is unclear, particularly in patients who present with fever and peritoneal signs, further testing is indicated. In these cases, computed tomography may rule out other causes of peritoneal clinical findings, such as appendicitis or diverticulitis, and in some cases, laparoscopy may be necessary to determine the cause of the patient’s illness.

### Differential Diagnosis

The differential diagnosis of lower abdominal pain in young women is broad in scope. Other common diagnostic consider-

### Management

The goal of treatment in PID is to prevent the chronic sequelae of infection. Treatment regimens must provide broad-spectrum coverage of likely pathogens, including N. gonorrhoeae, Chlamydia, anaerobes, gram-negative bacteria, and streptococci. Although endocervical testing is recommended in these patients, negative results do not preclude upper tract infection. Delaying treatment may increase the risk of developing long-term sequelae.

- No studies have clearly demonstrated differences in efficacy of parenteral versus oral therapy, or of inpatient versus outpatient treatment. The decision to hospitalize a patient must be based on the clinical presentation and other comorbid or complicating factors. The CDC suggests that any of the following criteria constitutes grounds for hospitalization:
  - Surgical emergencies such as appendicitis cannot be excluded.
  - The patient is pregnant.
  - The patient does not respond clinically to oral antimicrobial therapy.
  - The patient is unable to follow or tolerate outpatient oral regimens.
  - The patient has a severe illness, nausea and vomiting, or high fever.
  - The patient has a tubo-ovarian abscess.

It also has been recommended that patients with an intrauterine device be treated on an inpatient basis, on account of the high rate of adnexal inflammatory masses in this group.

Parenteral and oral regimens are listed in Table 96-5. If outpatient treatment is chosen, patients must be reevaluated within 24 to 48 hours to assess response to oral therapy. If there
is no response, the patient should be hospitalized for parenteral antibiotic therapy and confirmation of the diagnosis.

Patients should demonstrate significant clinical improvement, such as defervescence, decreased abdominal tenderness, and reduction in uterine, adnexal, and cervical motion tenderness, within 3 days of initiation of therapy. Sexual partners of patients diagnosed with PID should be evaluated and empirically treated for gonorrhea and chlamydial infection. Patients should be counseled to avoid sexual activity until both they and their partners have completed treatment. It is recommended by some specialists that patients with documented gonorrhea and chlamydial infection be reevaluated for test of cure in 4 to 6 weeks after completion of therapy, although this practice is not universal.

**KEY CONCEPTS**

- Patients with ulcerative genital lesions should be considered to have an STD and should be tested and treated accordingly.
- Patients with suspected gonorrheal infection also should be treated for chlamydial infection.
- Sexually active women with adnexal or cervical motion tenderness should be treated for PID.
- A single dose of azithromycin is inadequate to treat PID; patients require a 2-week course.
- Asymptomatic women with clue cells on wet mount preparations should not be treated for bacterial vaginosis.

- Pregnant women with bacterial vaginosis should not be treated if they are asymptomatic unless they are at risk for preterm labor or premature birth (i.e., if they have a history of preterm labor, miscarriage, or premature rupture of membranes).
- Patients with sexually transmitted infections are at risk for HIV infection and should be either tested in the ED or referred for HIV testing.

Chapter 97  Selected Urologic Problems

Kevin M. Ban and Joshua S. Easter

URINARY TRACT INFECTIONS

Perspective

Background. Urinary tract infection (UTI) describes an inflammatory response of urothelium to microorganisms in the urinary tract, resulting in clinical symptoms including dysuria, frequency, urgency, hematuria, and suprapubic or costovertebral angle discomfort self-reported by patient or later elicited on physical exam. This term does not differentiate between upper and lower tract infections. Traditionally, the emphasis has been on distinguishing lower tract from upper tract infections. Although this distinction may seem sensible from an anatomic perspective, it often does not provide additional information for making important management and disposition decisions. Bacteriuria is the presence of bacteria in the urine but is not considered to represent a UTI in the absence of clinical manifestations. Bacteriuria accompanied by symptoms should be treated, whereas bacteriuria in the absence of symptoms should be treated only in select patients (e.g., pregnant women).

It is more useful to designate UTIs as either being uncomplicated or complicated, rather than as lower or upper tract infections. An uncomplicated infection is one involving a structurally and functionally normal urinary tract. The causative pathogen generally can be eradicated with a short course of standard antibiotics. This type of infection usually occurs in nonpregnant, sexually active, young women who have no evidence of an obstructive process. Complicated infection is that associated with underlying neurologic, structural, or medical problems, all of which may reduce the efficacy of standard antimicrobial therapy. These types of infections often require a prolonged course of antibiotic therapy and a more in-depth approach to testing and anatomic evaluation.

Urethritis refers to the inflammation of the urethra secondary to either an infection or trauma. Frequently, urethritis may be a manifestation of a sexually transmitted disease (STD), such as gonococcal urethritis in Neisseria gonorrhoeae infection, but may occur in other clinical scenarios as well. Cystitis generally refers to inflammation of the bladder resulting in increased urinary frequency, urgency, dysuria, and suprapubic pain. Cystitis can be separated into bacterial and nonbacterial (e.g., radiation, trauma) etiologic categories. Acute pyelonephritis is a UTI of the renal parenchyma and collecting system manifested by the clinical syndrome of fever, chills, and flank pain. Management and disposition of patients with acute pyelonephritis depend on whether the infection is simple or complicated.

Epidemiology. UTI is a problem that affects all age groups. It is considered the most frequently occurring bacterial infection, accounting for 7 to 8 million annual outpatient visits, 1 million annual emergency department visits, 100,000 annual hospitalizations, and more than one third of all hospital-acquired infections. These statistics notwithstanding, gauging the actual extent of the disorder is very difficult because it is not a reportable disease in the United States and the definition of a UTI is not exact.

Women have a 20% chance of experiencing a UTI during their lifetime. The prevalence of UTIs is 2 to 4% among young, sexually active women and gradually increases to 5 to 10% by the age of 70 years and to approximately 20% by the age of 80 years.

UTIs account for 5 to 14% of pediatric ED visits in the United States. UTI is more common in boys during the neonatal period but becomes more common in girls during infancy and thereafter. When a UTI is seen in preschool boys, it is almost always associated with congenital anomalies of the urinary tract.

UTIs in adult men are uncommon unless cystoscopy or catheterization has been performed. The prevalence is less than 1% from childhood through middle age but increases to 1 to 3% by the age of 65 years and to 10% by the age of 80 years. Among institutionalized men and women, prevalence rates for bacteriuria and UTI are increased to approximately 25% and 40%, respectively. UTIs associated with presence of an indwelling catheter constitute the most common nosocomial infection in the United States, accounting for more than 1 million cases annually.

Principles of Disease

Physiology. The urine is sterile along the entire urinary tract from the glomerulus to the external sphincter in men and to the bladder neck in women. The urinary tract maintains its sterility by means of various defenses. A major mechanism is complete emptying. Free, unobstructed flow of urine within the kidney and down the ureter, coupled with complete evacuation of the bladder, is essential. Abnormal anatomy or physiology or the presence of a foreign body may compromise host defense mechanisms and predispose the patient to infection.

In men, the distal end of the urethra is inhabited by staphylococci, streptococci, and diphtheroid organisms. Nevertheless, men generally do not become infected without an underlying obstruction of normal urinary flow.
In women, the urethra is short and opens close to the vulvar and perirectal areas. The organisms that cause UTI in women usually arise from the fecal reservoir and initially colonize the vaginal introitus and periurethral area. These factors contribute in part to the much higher incidence of UTI in women.

Pathophysiology. Bacteria most often enter the urinary tract by ascent through the urethra and into the collecting system. Infrequently, bacterial infection of the urinary tract arises from hematogenous or lymphatic sources. This is the usual pathomechanism in debilitated and chronically ill patients who are immunosuppressed. Organisms from distal foci of infection like endocarditis or soft tissue sources may make their way through lymphatic or hematogenous channels, resulting in a UTI. In these patients, it is important to identify and treat the primary source of infection.

Numerous abnormalities of the urinary tract interfere with its innate ability to resist infection. Obstruction from any cause, with resultant stasis of urine, is the major etiologic factor. Any obstruction or impediment to the free flow of urine or complete bladder emptying results in an increased incidence of infection. Urinary calculi may cause obstruction and increased susceptibility to the development of UTI. It is crucial that infection in the setting of obstruction be diagnosed and relieved promptly.

Vesicoureteral reflux in children plays an important role in the pathogenesis of UTIs, particularly upper tract infections. Reflux caused by congenital abnormalities or by bladder overdistention (as seen in advanced prostatic hypertrophy) also predisposes affected patients to infection. Subgroups of patients who are more susceptible than the normal population to UTIs include diabetic patients, pregnant women, the elderly, patients with spinal cord injury and indwelling urinary catheters, patients with multiple sclerosis, and those with acquired immunodeficiency syndrome (AIDS) or human immunodeficiency virus (HIV) infection.

In young men, asymptomatic bacteriuria is rare and may signify urinary tract disease. UTIs in men generally begin to appear at 50 years of age (concomitant with the onset of prostatic hypertrophy) and slowly increase in incidence. The occurrence of UTI in men of any age warrants referral to a urologist for further evaluation.

Bacteriology. The organisms that cause UTIs generally come from enteric flora colonizing the patient’s perineum and urethra. *Escherichia coli* is the dominant pathogen in more than 80% of first infections in women, men, and children, as well as in 50% of nosocomial UTIs. *Staphylococcus saprophyticus*, a coagulase-negative gram-positive organism, is the second most common pathogen in UTI and accounts for approximately 11% of cases. This species is present in normal skin flora, including the perineal area, but only in low numbers, and it does not appear to be of fecal origin. Occasionally it is falsely identified as *Staphylococcus albus* or *Staphylococcus epidermidis*. Other, less common bacteria that may be responsible for infection include *Proteus*, *Klebsiella*, and *Enterobacter*. Unusual microorganisms may be found in institutionalized or hospitalized populations and with complicated UTIs. Such settings and conditions predispose the patient to alterations in the normal gastrointestinal flora, leading to complex UTIs. The uropathogens in these patients include more resistant strains of *Escherichia*, *Klebsiella*, *Proteus*, and *Enterobacter*, as well as *Pseudomonas*, *Enterococcus*, *Staphylococcus*, *Providencia*, *Serratia*, *Morganella*, *Citrobacter*, *Salmonella*, *Shigella*, *Haemophilus*, *Mycobacterium tuberculosis*, and fungi. Although not necessary with uncomplicated UTIs, urine culture and sensitivity testing are recommended for all patients with complicated UTIs. Antibiotic therapy based on the most likely pathogen should be initiated immediately.

Uropathogenic organisms may elaborate various factors that affect their virulence, including aerobactin, hemolysins, and fimbriae (pili). Fimbriae, also called adhesions, are proteinaceous structures that can attach to specialized receptor sites on host cells. Attachment of bacteria to vaginal and uroepithelial cells ultimately leads to a higher incidence of UTI.

Clinical Features

Signs and Symptoms. UTI is suspected in adolescents and adults on the basis of clinical findings including dysuria, frequency, urgency, and hematuria in the setting of suprapubic or CVA discomfort. Symptoms and signs will vary with age. In infants, initial manifestations may include irritability, fever, vomiting, diarrhea, and failure to thrive. Preschool children with UTI have vomiting, diarrhea, generalized abdominal pain, and febrile seizures. History of fever alone is not an adequate indicator of severity of infection in children because it may be historically absent in pediatric patients subsequently found to have significant renal scarring.

In general, clinical signs and symptoms associated with lower UTIs are localized to the genitourinary system and include urgency, dysuria, frequency, and suprapubic pain. In addition to these problems, a patient with an upper UTI may have back and flank pain as well as constitutional symptoms and signs such as fever, nausea, vomiting, and malaise. Clinical findings do not reliably differentiate between upper and lower tract infections. Stamm and coauthors report that 30 to 50% of women with signs and symptoms restricted to the lower urinary tract have silent (or subclinical) infection of the kidney.5

As discussed previously, it is more important to determine if the infection is simple or complex. Simple, uncomplicated infections do not require urine culture, may be treated on an outpatient basis, and may not always necessitate urinalysis when thought to represent isolated cystitis.17 Complicated infections require urine culture with antibiotic sensitivity and also may necessitate inpatient therapy or further diagnostic evaluation, or both.18 Distinction between upper and lower tract infections becomes important for understanding the differences in pathology and the pharmacokinetics of antibiotic delivery. Infection of the bladder generally involves only the superficial mucosa, and high urinary concentrations of antibiotics can easily be achieved with a short course of antibiotic therapy. The kidney, by contrast, tends to become infected in the medullary tissue, where achieving therapeutic concentrations of antimicrobial agents is far more difficult. As a result, parenteral antibiotics and longer courses of therapy are needed.

Men who complain of dysuria must be evaluated for the presence of urethral discharge before urinalysis is performed. In these patients, in whom the diagnosis of UTI is rare, the most likely etiologic disorder is an STD such as gonococcal or nongonococcal urethritis. If the patient has purulent urethral discharge, he should undergo testing for *Chlamydia trachomatis*, *N. gonorrhoeae*, and syphilis, as well as empirical treatment for STDs. If the patient does not have urethral discharge and complains predominantly of dysuria, frequency, urgency, and suprapubic or CVA discomfort, a urinalysis with culture should be performed. Male patients who have bacteriuria in the absence of clinical signs of urethritis or prostatitis should be considered to have a complicated UTI and should be treated with antibiotic therapy and receive urologic follow-up for further evaluation.
Laboratory Tests

Urine Collection Methods. The diagnostic value of microscopic examination depends on the quality of the specimen obtained. In neonates, suprapubic aspiration is a safe procedure for obtaining a urine specimen, but it is invasive. In neonates and children younger than 6 months, urethral catheterization is more often successful and, like suprapubic aspiration, carries a very low complication rate. Before catheterization is attempted in these younger patients, the ultrasound or bladder scanner can be used to confirm the presence of urine in the bladder. Collection of urine in a perineal “bag” is the least invasive method but is useful only if culture results are negative, because of high associated contamination rates.

In older children, a sterile midstream urine sample can be collected from boys. In girls, if the voided specimen is free of cellular elements (epithelial cells), it is acceptable for analysis. Catheterization often is a traumatic experience for children and one that invalidates their sense of privacy. An alternative approach to catheterization in a young girl with classic symptoms of UTI who has epithelial cells in the urine suggesting contamination is to evaluate the urine for other signs of infection. If the urine contains bacteria and red and white blood cells and is either nitrite- or leukocyte esterase–positive, the most likely cause of the symptoms is an uncomplicated UTI, for which antibiotic therapy and referral for follow-up care with the child’s pediatrician are indicated. If the clinical picture remains unclear and a definitive diagnosis is mandatory, straight catheterization is performed after examination of the child’s bladder with an ED ultrasound machine has confirmed the presence of urine.

Recommendations regarding urine collection methods in women vary widely. Midstream-voided specimens rarely escape perineal contamination, because for most adult women, adequate preparatory self-cleansing of the perineal area is difficult to achieve. It has been shown that in up to 50% of women with sterile bladder urine, a midstream clean-catch specimen grows 1000 to 100,000 bacterial colony-forming units (CFUs) per milliliter. This finding assumes major significance in the ED evaluation, in which accurate, initial supportive evidence for the diagnosis of UTI is crucial.

Sterile catheterization is the quickest and most accurate method of obtaining a urine specimen from an adult woman and may be the best solution for achieving a reliable urinalysis if the patient is actively menstruating. It is safe and relatively atraumatic and carries a remarkably low risk of infection. This risk increases if the patient is pregnant, elderly, or debilitated. If the clinician decides against catheterization, a clean-catch, midstream urine specimen should be sought. A predominance of epithelial cells suggests that the specimen is contaminated. The lower ratio of leukocytes to vaginal epithelial cells, the more likely it is that the leukocytes are vaginal contaminants.

In men, the specimen is not affected significantly by lack of cleansing or by the timing of specimen collection. Therefore, it is not appropriate to catheterize an adolescent or adult man simply for the purpose of collecting a urine specimen.

Urinalysis. Urine cultures constitute a majority of cultures performed by microbiology laboratories, and various screening tests have been developed for the purpose of reducing this burden and its attendant costs. The goal of urine screening tests is reliable selection of specimens that will provide negative cultures. This allows the laboratory to focus more appropriately on higher-yield studies.

The most commonly used screening tests measure urinary leukocyte esterase and nitrite. Leukocyte esterase is an enzyme found in neutrophils, and nitrite is produced from urinary nitrate by nitrate reductase, which is present in gram-negative bacteria. Both can be detected by a color change on dipstick testing. The two tests often are combined to improve overall accuracy. Indirect urine dipstick tests for pyuria or bacteriuria are inexpensive and easy to perform and may aid in establishing the diagnosis of UTI. They should be used with caution, however, because they can be less sensitive than microscopic examination of urine (urinalysis). Urine dipstick testing for leukocyte esterase has shown a sensitivity of 75 to 96% in detecting pyuria associated with UTI. By contrast, a meta-analysis of screening tests for UTI in children has demonstrated that dipstick testing for leukocyte esterase and nitrite may be equivalent to microscopic urinalysis for detection of UTI.

Symptomatic patients who have normal host defenses and demonstrate a positive result on leukocyte esterase testing (in the absence of other indications for urine culture) can be treated empirically without culture. In symptomatic patients, a negative result on tests for both leukocyte esterase and nitrite should be followed by urine microscopy. In adults, urine culture should be performed only if findings on the microscopic analysis also are negative or if the patient is at risk for bacteremia.

Urine Microscopy. Urine microscopy is another commonly used method of providing rapid results, thereby reducing the number of urine cultures performed. Up to 96% of infected urine specimens contain 10 or more white blood cells (WBCs) per cubic millimeter when counted by a hemocytometer. Various counting chamber methods detect pyuria with an accuracy approaching that of the hemocytometer. Unfortunately, these tests are not widely available, so direct microscopy commonly is used.

The accuracy of direct microscopy is compromised by a lack of standardization of the technique. Common sources of variability include specimen collection and transport, centrifugation speed and duration, decanting and resuspension techniques, staining, and the threshold used for significant numbers of WBCs or bacteria. One method, the slide centrifuge test, avoids many of these sources of error, and high sensitivity and specificity have been reported.

Although no accepted level of pyuria is diagnostic of UTI, on careful quantitation using a hemocytometer chamber, pyuria will be found in nearly all cases of acute UTI caused by coliforms. In patients with a low-count coliform infection, those with fewer than 8 WBCs/mm³ of urine will have no demonstrable infection. In patients with more than 8 WBCs/mm³, 85% will have documented infection (by the presence of coliforms, staphylococci, or chlamydiae). Despite these controversies and limitations, microscopic examination of urine to identify bacteria remains the most readily available and reliable test for a presumptive diagnosis of UTI in most patient populations. Any analysis of a urine sample must be performed immediately after collection. Urine specimens that are allowed to sit become alkaline, with subsequent dissolution of the cellular elements and multiplication of bacteria, thus providing the clinician with markedly unreliable results.

Urine Culture. Definitive diagnosis of UTI is based on isolation of significant numbers of bacteria on urine culture. Traditionally, growth of 10⁵ CFUs/mL has been used as the statistically significant number for the presence of UTI. Of note, however, using an absolute number is fraught with limitations. The presence of 10⁵ CFUs/mL of bacteria in cultures from urine is associated with a 95% likelihood of infection, whereas 10⁶ CFUs/mL is associated with a 50% likelihood of infection. It makes best clinical sense to put these results in clinical context regarding the presence of symptoms suggestive of a UTI. The
symptom complex of dysuria, frequency, urgency, and suprapubic pain may be caused by a wide variety of infectious organisms in numbers far less than the traditional 10^5 CFUs/mL. In addition, these same symptoms may represent a significant upper tract infection or may be caused by urethritis.

The presence of bacteria on culture in the absence of clinical manifestations does not always indicate infection. Women often carry large numbers of pathogenic bacteria on the perineum, and uncircumcised men may harbor large quantities of uropathogenic bacteria on the foreskin. The presence of bacteria in these regions may contaminate otherwise sterile bladder urine during collection.

The decision to perform a urine culture should be assessed for its relevance to patient care. Patients with frequency, dysuria, urgency, and suprapubic pain should be treated on the basis of symptoms only if the infection is thought to be simple. For women who have host factors (e.g., structural abnormalities) or comorbid conditions (e.g., compromised immune status, pregnancy) necessitating definitive identification of the organism by culture, both urinalysis and culture are necessary. In general, the list of indications for urine culture (Box 97-1) define high-risk groups. In vitro sensitivity testing contributes little to the general management of patients with uncomplicated UTI. Correlation between the therapeutic response and in vitro testing results often is poor. Culture also represents an additional cost with minimal contribution to the therapeutic plan for most outpatients.

**Imaging.** A majority of patients with acute cystitis or pyelonephritis do not need emergency imaging of the urinary tract. In certain clinical settings, however, emergency imaging is indicated. Patients with either unusually severe signs and symptoms or an atypical clinical presentation are candidates for genitourinary imaging. For example, a patient with the classic signs and symptoms of pyelonephritis but unremarkable urinalysis findings may have an obstructive process that has prevented the leukocytes and bacteria from reaching the bladder. Another example is that of a patient with a known history of UTI, currently receiving antibiotic therapy, who has persistent fever, chills, and general toxicity. Perhaps one of the most sensitive predictors of a complicated infection (e.g., abscess) is the persistence of fever beyond 72 hours after the institution of antimicrobial therapy. Pyelonephritis with obstruction from any cause can rapidly lead to abscess formation with resultant deterioration of renal function and sepsis. Emergency imaging is indicated to rule out this condition or to identify a suspected renal stone serving as a nidus for infection.

First episodes of UTI in selected patients, such as boys and girls younger than 4 years of age, generally require evaluation after resolution of the UTI. These patients are more likely than those in the general pediatric population to have structural anomalies and, if untreated, are at increased risk for recurrent UTI or for the development of complications such as hydronephrosis, renal scarring, and ultimately renal failure. The female patient with multiple episodes of complex infection, the patient with diminishing renal function, and the patient with renal colic and suspicion of obstructing stone, which progresses to sepsis, all require imaging.

Several imaging studies may be useful in these patients. Historically, intravenous or excretory urography—typically, intravenous pyelography (IVP)—was used because such studies provide both structural and functional information about the upper urinary tract. Recent work has focused on obtaining this information through safer, less invasive, and less costly methods. Ultrasonography compares favorably with IVP but is inferior to computed tomography (CT). Radionuclide cystograms compare favorably with voiding cystourethrograms in the diagnosis of vesicoureteral reflux and give less ionizing radiation to the gonads by a factor of 50 to 100. Voiding cystourethrography is the traditional method for initial evaluation of the genitourinary tract. CT scan is exceptional for diagnosing upper tract complications such as various degrees of pyelonephritis, abscesses, pyonephrosis, granulomatous infections, and infected cysts. As with IVP, its disadvantages include higher cost, radiation exposure, and potential for contrast-induced reactions.

**Ultrasonography.** Ultrasonography is useful in the evaluation of patients with potential urinary obstruction. It is a sensitive tool for detecting intrarenal and perinephric abscess and the presence of hydronephrosis. It is less accurate in determining the presence of a partially obstructing ureteral stone. Ultrasound examination also can detect the presence of pyelonephritis and congenital anomalies. Regardless of patient age group, this procedure is relatively inexpensive and avoids the hazards of contrast and radiation exposure.

**Intravenous Pyelography.** IVP, previously considered one of the mainstays in the evaluation of the genitourinary tract, has been nearly replaced by helical CT scanning and ultrasonography. IVP has higher sensitivity and specificity for determining the presence of obstruction than ultrasound examination but is inferior to CT scanning, and it is not sensitive for detecting the presence of pyelonephritis and renal abscess.

**Radionuclide Scans.** Radionuclide scans also are gaining popularity for the early evaluation of UTI. A dimercaptosuccinic acid scan is the most sensitive method of identifying pyelonephritis and is the imaging study of choice in infant girls with UTI and fever.

**Computed Tomography of the Abdomen.** A contrast-enhanced CT scan of the abdomen is perhaps the best test for assessing the kidneys, ureters, and bladder. It has the highest sensitivity for detecting abscess, obstruction, and acute inflammation. Its disadvantages include cost, radiation exposure, and potential for contrast-induced reactions and radiocontrast agent–induced acute renal injury. CT without contrast can be performed in
patients with renal insufficiency and is the preferred study in patients with clinical concern for urolithiasis.

Complicated Urinary Tract Infection in High-Risk Populations

Pregnancy

UTI during pregnancy represents a special situation. The incidence of UTI in pregnancy is approximately 2 to 7%. Maternal complications include acute pyelonephritis, increased incidence of postpartum chronic pyelonephritis, preterm delivery, and low newborn birth weight. The physiologic changes that occur within the urinary tract of pregnant women include ureteral and renal pelvis dilatation, as well as reduced peristalsis throughout the collecting system. During the last trimester, minimal ureteral contractions occur in many patients.

Unlike bacteriuria in nonpregnant females, bacteriuria in pregnant women, even if they are asymptomatic, must be treated. Complications that may result from untreated bacteriuria in pregnancy include premature labor, perinatal mortality, maternal anemia, and maternal pyelonephritis.

Reasonable antibiotic choices include amoxicillin, cephalaxin, and nitrofurantoin. Trimethoprim-sulfamethoxazole (TMP-SMX) may be used before the third trimester. Single-dose therapy is not recommended, because these are not considered simple infections. Hospital admission should be considered in patients who are in their last trimester, who appear ill, or who have evidence of pyelonephritis and intravenous fluids. Although pregnant patients with UTI are being treated on an outpatient basis more frequently than in the past, conservative treatment and close follow-up are warranted.

Diabetic Sickle Cell Disease

Diabetic patients with bacteriuria also have an increased risk for the development of pyelonephritis, but treatment of asymptomatic bacteriuria has not been proved to be beneficial and should not be standard therapy at this time.26 Papillary necrosis, perinephric and renal abscess formation, and emphysematous cystitis represent grave complications for this patient group. Manifestations of these complications may include altered vital signs, systemic signs and symptoms such as nausea and vomiting with dehydration, and a toxic appearance suggesting bacteremia and sepsis. These patients require aggressive fluid resuscitation, intravenous antibiotics, and a thorough diagnostic investigation including CT scanning.

Patients with sickle cell anemia also have shown a predilection for the development of papillary necrosis and generalized renal microvascular compromise. In these patients, compromised renal function is thought to be secondary to microvascular damage from the chronic sickling of their erythrocytes. The renal damage from a UTI can compound the chronic renal insufficiency, leading to rapid worsening of their condition. These patients and all patients with underlying kidney disease or renal compromise should be approached conservatively, with hospitalization as deemed necessary for intravenous hydration and antibiotics.

Presence of an Indwelling Catheter

Treatment of asymptomatic bacteriuria in patients with indwelling catheters is not indicated. Antibiotic treatment results in the development of resistant microorganisms, whereas removal of the catheter leads to the spontaneous elimination of bacteria in many patients. Treatment of patients with a UTI in whom removal of the catheter is contraindicated includes urine culture and sensitivity, antibiotic therapy, replacement of the catheter, and strong consideration for hospitalization in those who exhibit altered vital signs, systemic symptoms, or a toxic appearance. These patients are at high risk for infection with an unusual pathogen and subsequent bacteremia. Urine culture with antibiotic sensitivity testing will help guide antibiotic therapy in this patient population.

Differential Considerations

Bacterial UTI is the most common cause of dysuria, with low-count infections. It is important, however, to consider the possibility of acute urethritis or acute vaginitis in these patients, as well as mechanical trauma or irritation (Tables 97-1 to 97-3; Fig. 97-1). Urethritis caused by Chlamydia may be seen in patients with acute dysuria; in fact, C. trachomatis may be present in up to 20% of women with dysuria. In general, if historical information includes contact with multiple sexual partners, a recent change in sexual partners, or a sexual partner with dysuria or discharge, C. trachomatis infection should be strongly considered. A pelvic examination should be performed, and culture specimens should be obtained to detect C. trachomatis and N. gonorrhoeae. Other causes of acute dysuria include infections with Trichomonas vaginalis and herpes simplex virus.

The dysuria of vaginitis most often is described as “external,” the sensation being caused by the passage of urine over inflamed introital tissue. Elderly women may complain of dysuria secondary to atrophic vaginitis. In either case, a pelvic examination may be required. Urinary frequency and urgency are seldom if ever associated with a vaginal cause of dysuria.

Bacterial infection of the bladder is the most likely cause of dysuria in female patients. Most demonstrate positive results on urine cultures, with growth of more than 10^5 CFUs/mL of bacteria. This number is not absolute, because 30 to 50% of patients have low-count bacterial infections as a cause of their symptoms. It has been suggested that low bacterial counts may represent an early phase of UTI.

Management

Simple Urinary Tract Infection

Options for treating uncomplicated lower UTI include single-dose therapy, short-course therapy (3 to 5 days), and the more traditional 7- to 10-day course of therapy (Table 97-4). E. coli remains the most common urinary tract pathogen and is susceptible to many antibiotic regimens. Emerging resistance to TMP-SMX has been noted in up to 32% of organisms.27 In some areas of Europe, resistance to TMP-SMX is approaching 50%.28 Risk factors for UTI from TMP-SMX–resistant E. coli include recent use of antibiotics (especially TMP-SMX), recent travel to areas with a high prevalence of resistance, and age younger than 3 years with day care attendance.29

Three days of therapy is more effective than single-dose therapy. The longer-duration regimen shares the advantages of improved compliance, lower cost, and reduced side effects. It currently is the recommended regimen for treatment of uncomplicated lower UTI. Despite emerging resistance, TMP-SMX remains the best first-line agent for 3-day regimens when compared with other commonly used antibiotics, owing to its low cost and effectiveness.29,30 Short-course 3-day therapy also is effective for asymptomatic bacteriuria in pregnancy. It is unclear whether this regimen can be used for symptomatic lower UTIs in pregnancy, so longer-course
therapy is recommended. Seven- to 10-day therapy generally offers no benefit over shorter courses in uncomplicated UTIs; however, it remains the standard of care in complicated infections (in patients with pregnancy, diabetes, or sickle cell anemia) for which cure rates are lower with shorter regimens.

The fluoroquinolones are considered first-line agents in regions in which the incidence of TMP-SMX resistance has approached 10 to 20%. Ciprofloxacin is the most commonly used drug and requires twice-daily dosing. Although more expensive than ciprofloxacin, gatifloxacin and levofloxacin offer once-daily dosing, have the broadest activity, and have same-dose bioequivalence between oral and parenteral administration. Fluoroquinolones damage developing cartilage in animal studies and should be avoided in children.

Nitrofurantoin and trimethoprim are excellent drugs for the treatment of acute bacterial cystitis. Nitrofurantoin is inexpensive and maintains low serum and high urine levels, with a bacterial resistance pattern that remains unchanged. Adverse reactions are primarily secondary to gastrointestinal disturbance, but they may be alleviated by using the macrocrystalline form (Macrodantin). Folate antagonists such as trimethoprim have a broader spectrum of activity than that of nitrofurantoin. The addition of sulfamethoxazole further broadens the spectrum to include coverage for Proteus and Klebsiella. Folate antagonists carry a higher incidence of adverse

effects than nitrofurantoin, predominantly gastrointestinal upset, yeast vaginitis, and rash. Addition of the sulfa component further increases the likelihood of side effects.

Except in pregnancy, ampicillin and amoxicillin should not be used empirically as first-line drugs for the treatment of uncomplicated UTI. Recurrence rates with use against ampicillin-resistant strains are high, and neither agent effectively eradicates the vaginal reservoir of pathogenic bacteria.

A useful adjunctive therapy for UTIs is phenazopyridine (Pyridium). It produces topical analgesia in the urinary tract and helps relieve dysuria. Patients should be cautioned that body secretions and excretions (e.g., tears, urine) will turn orange. This side effect can stain contact lenses and alarm unknowing patients.

Complex Urinary Tract Infection

Mild to moderate pyelonephritis can be safely treated on an outpatient basis with a fluoroquinolone for 10 to 14 days (first-line agent) or TMP-SMX (second-line agent) so long as the patient is able to eat and drink, has achieved adequate pain control, and has appropriate psychosocial support in the home. In many clinical centers, observation units have evolved to offer a short-stay (less than 24 hours) option for moderate cases in which immediate discharge for outpatient therapy may not be the optimal approach to management.

Severe upper tract UTI necessitating hospitalization initially should be treated with parenteral antibiotics, with transition to oral therapy after the patient has been afebrile for 24 to 48 hours. Oral therapy should be continued for 2 weeks. Because 20% of cultures are resistant to ampicillin, cephalothin, and sulfonamides, antibiotic therapy should be initiated with a fluoroquinolone.

Hospitalization is required in the presence of clinical toxicity (fever, tachycardia, hypotension, vomiting), inability to take oral medications, an immunocompromised state, third trimester pregnancy, inadequate social circumstances, failure of oral outpatient therapy, or urologic abnormalities or in patients with significant comorbid conditions including heart failure, renal insufficiency, and compromised immune status.

A subgroup of patients suffering from upper tract UTI do not require immediate hospital admission but may benefit from intravenous hydration and pain and fever control, along with a first dose of an intravenous fluoroquinolone. If these patients do not have any contraindications as previously discussed and they improve clinically and are able to tolerate food and drink, they can be safely discharged home on a 10- to 14-day course of an oral fluoroquinolone with close primary physician follow-up. Urine culture with sensitivity testing and further diagnostic evaluation are not necessary in this patient population.

■ URINARY TRACT INFECTION IN CHILDREN

Perspective

UTI is a major bacterial disease of childhood; it is estimated that 0.8 to 1.5% of children have bacteriuria. The risk for development of UTI before 11 years of age is 3% in girls and 1% in boys. The incidence of UTI in the neonatal period is higher in boys, but the infection becomes more prominent in girls during infancy and thereafter. In children aged 1 to 3 months, UTI is associated with a high incidence of sepsis (30%). After the age of 3 months, the incidence of sepsis associated with UTI decreases (to 5%). Vesicoureteral reflux is a common risk factor for UTI and renal scarring in children.

*Treatments listed are those to be prescribed before the etiologic agent is known (Gram staining can be helpful); they can be modified once the agent has been identified. These recommendations are limited to drugs currently approved by the U.S. Food and Drug Administration, although not all of the regimens listed are approved for these indications. Fluoroquinolones should not be used in pregnancy. TMP-SMX, although not approved for use in pregnancy, has been widely used. Gentamicin should be used with caution in pregnancy because of its possible toxicity to eighth nerve development in the fetus.*

†Multiday oral regimens for cystitis are as follows: TMP-SMX, 160 to 800 mg every 12 hours; trimethoprim, 100 mg every 12 hours; norfloxacin, 400 mg every 12 hours; ciprofloxacin, 250 mg every 12 hours; ofloxacin, 200 mg every 12 hours; lomefloxacin, 400 mg every 12 hours; enoxacin, 400 mg every 12 hours; macrocrystalline nitrofurantoin, 100 mg four times a day; amoxicillin, 250 mg every 8 hours; and cefpodoxime proxetil, 100 mg every 12 hours.

‡Oral regimens for pyelonephritis and complicated UTI are as follows: TMP-SMX, 160 to 800 mg every 12 hours; norfloxacin, 400 mg every 12 hours; ciprofloxacin, 500 mg every 12 hours; ofloxacin, 200 to 300 mg every 12 hours; lomefloxacin, 400 mg every day; enoxacin, 400 mg every 12 hours; amoxicillin, 500 mg every 8 hours; and cefpodoxime proxetil, 200 mg every 12 hours.

Data suggest that the incidence of scar formation after acute pyelonephritis may be as high as 37%.

**Principles of Disease**

As in adults, *E. coli* is the predominant pathogen. Age-related differences are recognized: In older boys, *Proteus* often is isolated during UTI, whereas in newborn children, *Klebsiella* often is the causative agent. The route of infection also is age-related. In the newborn period, it is thought that the bacteria are blood-borne (and often associated with generalized sepsis). In the older age group, as in adults, the ascending urethral route is primarily responsible for generating infection of the urinary tract.

**Clinical Features**

UTI often is overlooked in children because of inappropriate emphasis on classic signs and symptoms, with little regard to age variables. Nonspecific findings should be considered the rule and not the exception (Table 97-5). Pyelonephritis may be present without overt symptoms. A UTI in a febrile patient usually indicates pyelonephritis. An elevated BUN level or hypertension in a child older than 2 months strongly suggests bilateral hydronephrosis or advanced renal parenchymal disease.

**Neonates**

Generalized septicemia often is the major manifestation of neonatal UTI. Classically, feeding difficulties, irritability, and sluggishness are seen in this age group. Bacteremia is present in nearly 50% of cases.

**Age 1 Month to 3 Years**

This age group has the most deceptive clinical presentation of UTI. Nonspecific findings are typical: fever, irritability, abdominal pain, vomiting, and failure to thrive. Occasionally, gross hematuria may be present.

### Diagnostic Strategies

Laboratory studies useful for diagnosing an infection of the urinary tract as previously described also apply to children. However, presumptive treatment may be indicated in high-risk patients based on clinical predictors and screening tests, as shown in Figure 97-2. Additional studies are dictated by the clinical setting and include renal function studies, a complete blood count, serum electrolyte panel, CT scan, voiding cystourethrogram, and ultrasonography. Renal cortical scintigraphy has proved to be the most sensitive method of detecting pyelonephritis.

Urine collection often poses a challenge in a child with a suspected UTI. The following techniques represent acceptable methods of urine collection:

- **Urethral catheterization** is appropriate for all infants. Aseptic technique ensures a low risk of introducing bacteria. It is the preferred method of urine collection.
Suprapubic aspiration is a superb reliable method if urine is available to be withdrawn, but it is seldom used these days. For patients 12 months or younger, it is a useful method and carries an incidence of adverse effects similar to that of urethral catheterization.

Plastic bag collection is a reasonably reliable method, but the perineum (in girls) and the glans (in boys) should be properly cleansed before application of the bag. It is a less reliable form of collection and is associated with a high incidence of skin contamination.

A clean-catch urine specimen is preferred in cooperative and continent male patients.

Management and Disposition
As in adults, many therapeutic options are available for children with UTI. Sulfonamides, nitrofurantoin, TMP-SMX, cephalosporins, and aminopenicillins all are effective. Newborns and young infants should be treated with ampicillin and gentamicin on an inpatient basis, and sulfonamides should be avoided. Traditionally, inpatient treatment with parenteral antibiotics has been the standard of care for young children. T raditionally, inpatient treatment with parenteral antibiotics has been the standard of care for young children. The child should be seen for follow-up 2 to 3 days after the onset of therapy is acceptable in children with uncomplicated infection. If hospitalization is required, hospital admission is advised for children who are dehydrated, severely ill, or not tolerating oral fluids or those with underlying structural abnormalities of the genitourinary system. In addition, family dynamics, which could affect compliance with medication, should be taken into account in decisions regarding the disposition of the case of a child with a UTI.

The appropriate duration of therapy currently is a subject of debate. Many experts believe that in children with uncomplicated lower UTI, short-course therapy can be used instead of the traditional 10-day regimen. Short-course (3-day) therapy is more widely accepted in adolescent girls. Once the decision to discharge a child has been made, the parents should be advised of signs of toxicity and the importance of compliance with medications. Parents should bring the child to the ED immediately if signs of toxicity develop and should arrange routine follow-up with the pediatrician if the child improves. The child should be seen for follow-up 2 to 3 days after the ED visit and again 2 to 3 weeks later (or 7 to 10 days after completion of the antibiotic course).

URINARY TRACT INFECTION IN MEN
Perspective
The incidence of UTI is much lower in men than in women. The route of infection in men generally is ascending, from the urethra to the prostate, bladder, and kidney. Pathogenic organisms responsible for UTI in men are similar in type, regardless of the site of infection in the genitourinary tract. E. coli causes 80% of infections in men. UTI in men should always be considered a complicated infection and mandates more extensive evaluation as well as a longer course of antibiotics.

Specific Disorders
Cystitis
Cystitis is rare in male patients in the absence of trauma, prostate pathology, or instrumentation. Chronic prostatitis, prostatic hyperplasia with obstruction, and previous instrumentation are the most common predisposing factors. Lack of circumcision and homosexuality are other recognized risk factors. Commonly, men with cystitis have symptoms of urinary urgency, frequency, dysuria, nocturia, suprapubic pain, and often low back pain. Gross hematuria occasionally occurs, but fever, chills, and flank pain generally are absent. On physical examination, suprapubic tenderness to palpation may be elicited. Pneumaturia may be present and is indicative of an infection with gas-forming bacteria. It also may indicate the presence of a vesicoenteric fistula, which often is caused by diverticulitis, although rectosigmoid carcinoma and regional enteritis are associated diseases as well. If fever and chills are present in association with irritative symptoms and difficulty voiding, acute bacterial prostatitis should be strongly considered. The most common pathogens found in men with cystitis are E. coli, Proteus, and Providencia.

A voided urine specimen should reveal pyuria, bacteriuria, and a variable degree of hematuria. Urine culture is essential. If there are no signs of toxicity, the patient generally can be treated on an outpatient basis with any of the urinary antibacterial agents (TMP-SMX, nitrofurantoin, sulfonamides, or fluoroquinolones).

Three qualifying factors must always be addressed in dealing with UTIs in men:

1. Obstruction. It is imperative that urinary obstruction be ruled out as a pathogenic mechanism. Infection and obstruction together can be catastrophic and lead to sepsis. Obstruction at the level of the prostate in older men is common and should be considered. Catheterization or bedside ultrasound examination may be indicated to rule out retention. Suggestion of obstruction of the upper tracts based on history necessitates performance of an abdominal CT scan without intravenous contrast or ultrasound.

2. Genitourinary tract anomalies. UTIs in men often are secondary to underlying, serious disease of the genitourinary tract. Therefore, all of these patients should be referred to a urologist for diagnostic studies.

3. Catheterization. Urethral catheterization should not be used to collect a urine specimen in men unless they are experiencing urinary retention. An inability to produce a specimen in the presence of infectious symptoms should be a major clue regarding the cause of the infection. If retention is suspected, catheterization for collection of residual urine is indicated. Referral for urologic consultation is mandatory and hospital admission is prudent for a majority of these patients.

Pyelonephritis
Clinical features in men with acute pyelonephritis include flank and costovertebral angle pain, chills and fever, urinary frequency, urgency, and dysuria. Generalized malaise, nausea, and vomiting are early signs of systemic toxicity, suggesting impending gram-negative sepsis. These patients require hospitalization for intravenous hydration and antibiotic therapy, as well as pain and fever control.

A voided urine specimen usually reveals leukocytes, occasional leukocyte casts, a variable number of red blood cells (RBCs), and bacteria. Urine culture is essential in this patient population. Blood cultures should be performed if the clinical picture suggests sepsis. A complete blood count, renal function studies, and electrolyte studies are recommended. Uncomplicated pyelonephritis should not produce detectable alterations in the BUN level. In males, imaging with ultrasonography or abdominal CT without contrast is required, because the etiology typically involves obstruction secondary to a stone, prostate pathology, stricture, or tumor. Catheteriza-
tion for collection of residual urine may be indicated if urinary retention is suspected.

Prostatitis

Bacterial prostatitis is an infection of the prostate caused primarily by gram-negative organisms. More than 80% of cases are caused by strains of *E. coli*; the remainder are caused by *Klebsiella*, *Enterobacter*, *Proteus*, and *Pseudomonas* species. Patients with prostatitis may complain of dysuria and perineal and low back pain associated with fever, chills, and malaise. A rectal exam must be part of the workup in all men who complain of symptoms suggestive of cystitis. Bacterial prostatitis is not a subtle disease, and patients will have an exquisitely tender and boggy prostate.

Acute bacterial prostatitis is an acute febrile illness characterized by chills, low back pain, and perineal pain. Irritative symptoms of voiding, including frequency, urgency, and dysuria, are present, along with various degrees of bladder outlet obstruction and retention. Patients often have constitutional symptoms of arthralgia, myalgia, and generalized malaise. Prostate examination reveals a tender, swollen gland that is firm and warm to touch. Palpation of an acutely inflamed prostate should be limited, to avoid the possibility of precipitating bacteremia or sepsis. Cystitis usually accompanies acute bacterial prostatitis. Thus, culture of voided bladder urine generally reveals the responsible pathogen.

Antimicrobial therapy has been shown to be beneficial and is recommended. In patients without signs of systemic toxicity, a prolonged course of an antibiotic for 4 to 6 weeks is recommended.34 However, if only partial success is achieved, the following list represents an appropriate selection of drugs for nontoxic prostatitis:

1. Ciprofloxacin, 500 mg orally twice daily; norfloxacin, 400 mg orally twice daily; or ofloxacin, 400 mg by mouth twice daily for 30 days
2. Trimethoprim with sulfamethoxazole (Bactrim), one double-strength tablet by mouth twice daily for 30 days

If the patient is toxic-appearing with fever, chills, or urinary retention, hospitalization and parenteral antibiotics are warranted. The following antibiotic choices are appropriate for toxic prostatitis:

1. Ciprofloxacin, 400 mg IV every 12 hours, or levofloxacin, 500 mg IV every 24 hours
2. Ceftriaxone, 2 g IV every 24 hours with or without gentamicin 3 to 5 mg/kg per day

If the patient is experiencing painful urinary retention, urethral catheterization should be avoided. Suprapubic needle aspiration or catheterization is much safer and more comfortable than urethral catheterization for initial management. A urologist should be consulted regarding management of all patients requiring suprapubic tube placement.

General support measures for outpatients should include bedrest, analgesics, antipyretics, hydration, and stool softeners.

Chronic Prostatitis

Patients with chronic prostatitis typically present to the ED when they experience an acute exacerbation of the disease. Clinical manifestations vary widely, but most patients complain of some degree of irritative voiding symptoms (frequency, urgency, dysuria), low back and perineal pain, and occasionally myalgias. Fever and chills are uncommon except during an acute exacerbation of the chronic infection. A history of previous episodes of acute prostatitis may be absent. Findings on the physical examination, including examination of the prostate, often are unremarkable. The hallmark of chronic bacterial prostatitis is relapsing UTI caused by the same organism. Chronic bacterial prostatitis is the most common cause of recurrent UTI in men.

Antimicrobial therapy is recommended for the treatment of chronic prostatitis. Unfortunately, most antimicrobials diffuse poorly from plasma into prostatic fluid. The fluoroquinolones achieve the highest concentrations in the prostate and are the drugs of choice, with cure rates of approximately 64%. The recommended dosages are as follows: ciprofloxacin, 500 mg twice daily for 30 days; norfloxacin, 400 mg twice daily for 30 days; enoxacin, 400 mg twice daily for 30 days; or ofloxacin, 300 mg twice daily for 6 weeks. TMP-SMX also is useful, with cure rates of 44 to 50%. The dosage is one double-strength tablet twice daily, but the optimal duration of therapy is unclear and may range from 4 to 16 weeks.

## RENAL CALCULI

### Perspective

**Background.** Renal calculi constitute a common clinical problem seen in the ED. From 1994 through 2000, presentations for urolithiasis nearly doubled, and all indicators point to a rise in the incidence of kidney stones in the general population.37 Renal calculi are seen commonly in young adults and middle-aged men, with nearly 70% of all ureteral calculi occurring between the ages of 20 and 50 years. Most ureteral calculi originate in the kidney and then pass into the collecting system.

**Epidemiology.** Various clinical syndromes involve metabolic alterations and are therefore associated with an increased likelihood of stone formation (Box 97-2). Risk factors include age, male gender, and family history. In the United States, prevalence rates for renal calculi are 7% in men and 3% in women.

### Principles of Disease

**Overview.** Multiple pathogenic factors interact to cause the formation of renal calculi. Renal calculi can be stratified into the following types: calcium, struvite, uric acid, and cystine.

UTI, urinary tract infection.
Most stones (75%) are composed of calcium oxalate, alone or in combination with calcium phosphate. Hyperecretion of calcium is a major contributor to stone formation and occurs in various clinical settings. The major dietary sources of calcium are cheese and milk, and hypercalciuria may occur in adults who ingest more than 1 quart of milk daily. Many conditions are associated with the development of hypercalciuria with increased risk of stone formation. Perhaps the most common is hyperparathyroidism, in which calculi develop in 67% of patients. Peptic ulcer disease also may be a predisposing factor. These patients tend to ingest large amounts of calcium with food, in addition to absorbed alkali sources (sodium bicarbonate) and antacids. The other major component of calcium stones, oxalate, also is influenced by diet. Hypermagnesuria occurs in the presence of small bowel disease—Crohn’s disease, ulcerative colitis, and radiation enteritis.

Magnesium-ammonium-phosphate (struvite) stones account for approximately 15% of all renal calculi. Struvite stones occur almost exclusively in patients with UTI and often are referred to as “infection stones.” They form as a result of urea-splitting organisms such as Proteus, Providencia, Klebsiella, Pseudomonas, and Staphylococcus. Distinctive features of these stones include common occurrence as staghorn calculi and the formation of “coffin-lid” crystals, often in the presence of alkaline urine.

Uric acid stones account for 10% of all stones in the United States. The basic causative factor is excessive excretion of uric acid in urine. Approximately 25% of patients with symptomatic gout have uric acid calculi, and the incidence of uric acid stones increases with the use of uricosuric agents. A distinctive feature of uric acid stones is their radiolucency. These stones infrequently take the form of staghorn calculi.

Cystine stones are rare and account for only 1% of stones. They are caused by an inborn error of metabolism that results in increased secretion of cystine and often occur as staghorn calculi.

Pathophysiology. Impaction along the genitourinary tract is a serious complication of renal calculi and can cause several physiologic changes. Once obstruction occurs, a rapid redistribution of renal blood flow results in a decrease in the glomerular filtration rate. As glomerular and tubular function decreases, renal excretion shifts to the unaffected kidney. Obstruction also causes a rapid decrease in ureteral peristaltic activity. In the presence of infection, both renal and ureteral function may be impaired. Complete obstruction of the ureters may lead to loss of renal function, with an increased incidence of irreversible damage after 1 to 2 weeks, including rupture of the renal calyx. Partial obstruction is associated with a lower likelihood of renal injury, but it may still result in irreversible damage.

Although calculus size and location are important determinants of the degree of disease, the major cause of progressive renal damage is associated infection. The stone behaves as a foreign body and leads to stasis and obstruction, decreasing host resistance and increasing the incidence of infection. Subsequent infectious complications include pyelonephritis, perinephric abscess, and gram-negative bacterial sepsis.

The three primary predictors of stone passage without the need for surgical intervention are calculus size, location and the degree of patient pain at discharge. The most important factor that relates to passage of a calculus through the genitourinary tract is its size. Approximately 90% of stones smaller than 5 mm pass spontaneously within 4 weeks. This number decreases to 15% for stones between 5 and 8 mm. Up to 95% of stones larger than 8 mm become impacted along the genitourinary tract, and lithotripsy or surgical removal often is required. Unless the stone is infected or renal damage is considerable, surgical intervention can be performed on an outpatient basis, provided that the patient is able to tolerate oral intake and adequate pain control can be obtained. Spontaneous passage is more frequent with stones located below the midureter than with those located above the midureter. Patients with well-controlled pain on discharge are less likely to require surgical intervention than those who do not have well-controlled pain.

Renal calculi seldom cause complete obstruction. There are five sites along the ureter at which calculi are likely to become impacted (Fig. 97-3). First, a stone may lodge in the calyx of the kidney or pass into the renal pelvis and become lodged at the ureteropelvic junction. The relatively large renal pelvis (1 cm) narrows abruptly at its distal portion, where it is equal in diameter to its adjoining ureter (2 to 3 mm). The third region is near the pelvic brim where the ureter arches over the iliac vessels posteriorly into the true pelvis. The most constricted area along the ureter, and a common location for impaction, is at the ureterovesicular junction. This location is the site at which the ureter enters the muscular coat of the bladder (intramural ureter). At the time of diagnosis, up to 75% of stones are located in the distal third of the ureter. Finally, calculi may become lodged in the vesical orifice.

Clinical Features

Signs and Symptoms. The onset of pain usually is abrupt, with a crescendo of extreme pain that begins in the flank, extends laterally around the abdomen, and radiates into the groin. Pain may radiate to the testicles in men and the labia majora in

women. A constant, underlying dull ache in the flank is common between episodes of colic. The cause of colicky, severe flank pain is hyperperistalsis of the smooth muscle of the calyces, pelvis, and ureter, whereas the cause of a dull ache can be acute obstruction and renal capsular tension.

Autonomic nerve fibers that serve the kidney, testicle, and ovary are involved in the transmission of pain with renal calculi, and the location of the stone may be suggested by the pattern of pain. A stone located high in the ureter may cause pain that radiates to the testicle (or ovary). As the stone approaches the bladder, the pain may shift to the scrotum or vulva. Symptoms of urinary urgency and frequency often develop as the stone nears the bladder.

Gastrointestinal symptoms of nausea and vomiting are common in patients with renal colic. A third of patients experience gross hematuria, with or without blood clots in the urine. A history of fever and chills strongly suggests superimposed infection; such cases should be regarded as a true urologic emergency.

**Physical Examination.** A patient with renal colic often is in severe pain and paces or writhes in pain on the stretcher, unable to find a comfortable position. The skin usually is pale, cool, and clammy. Fever generally is not noted but if present strongly suggests infection. The abdominal examination may reveal signs of an early ileus with hypoactive bowel sounds. A decrease in peristalsis often accompanies renal colic, but abdominal tenderness usually is absent and flank tenderness is more common. It is essential that the abdomen be auscultated and palpated in search of bruits and thrills over the abdominal aorta and iliac vessels, because the clinical manifestations of aortic abdominal aneurysms may mimic those of renal colic. Patients commonly have intermittent pain that may nearly resolve between episodes of severe discomfort. The clinical picture may be misleading, with the patient’s repeated attempts to secure relief from the pain misinterpreted as drugseeking behavior, whereas actual pathology requiring medical attention is present.

**Diagnostic Strategies**

**Laboratory Tests**

**Urinalysis.** The initial diagnostic step in the management of suspected renal colic is urinalysis. This simple, noninvasive test provides helpful information on various aspects of the patient’s condition. Generally, a dipstick test is performed first to evaluate for the presence of blood and infection. If results are abnormal, it is usually followed by microscopic analysis.

**Sediment Analysis.** RBCs generally are found in the urine of patients with urolithiasis. However, the absence of RBCs in urine does not exclude the diagnosis. From 10 to 20% of patients with documented urolithiasis have no microscopic hematuria. Furthermore, there is no correlation between the degree of obstruction and the absence of hematuria. Although sterile pyuria can occur in the absence of infection as the result of ureteral inflammation, the presence of a UTI should be investigated if other clinical signs of infection are present, such as fever and chills. A urinalysis with culture should always be performed to look for pyuria and bacteriuria and to measure nitrites and leukocyte esterase when infection is suspected.

**Urinary pH.** The kidney will not produce urine with a pH greater than 7.5 under normal conditions, so urinary pH greater than 7.5 should raise suspicion for the presence of urea-splitting organisms such as *Proteus*. Renal tubal acidosis and ingestion of absorbable alkali also may increase urine pH and must be considered in the differential diagnosis. A pH less than 5 often is associated with the formation of uric acid calculi.

**Crystalluria.** Historically, examination of urine crystals present on microscopic evaluation has provided a clue to the type of stone present. As a result of consolidation of urine testing to a central laboratory in most hospitals, this test is no longer routinely performed in most EDs.

**Other Laboratory Tests.** Serum uric acid levels are elevated in 50% of all uric acid stone formers, but this determination is not mandatory in the ED evaluation of the patient. Measurement of BUN and serum creatinine levels is not routine but should be done in patients who have a renal calculus with a solitary kidney, a transplanted kidney, or a history of renal insufficiency. A complete blood count may reveal a slightly elevated WBC count in patients with renal calculi which may be due to demargination, but this is not a sensitive test and should only be performed in patients who are thought to be infected. A WBC count higher than 15,000/mm³ or a significant left shift on the differential suggests active infection. Serum calcium and phosphorus levels can help screen for hyperparathyroidism, sarcoidosis, and other disorders of calcium metabolism, but this metabolic workup is not a necessary component of the ED evaluation of nephrolithiasis.

**Imaging.** Imaging is not needed in all patients with renal colic. If the signs and symptoms are atypical, the diagnosis is in question, the patient appears toxic, high-grade obstruction is suspected, or it is the patient’s first episode of flank pain, imaging should be performed.

**Computed Tomography.** Non–contrast-enhanced helical (spiral) CT scan is the standard imaging modality in the United States. It is sensitive and specific (97% and 96%, respectively) in detecting both ureteral calculi and ureteral obstruction. Other advantages include its ability to detect calculi as small as 1 mm in diameter and to provide direct visualization of complicating conditions such as hydronephrosis, edema (Fig. 97-4), and ureteral edema. The CT scan is superior to other imaging modalities in its ability to recognize other pathology (malignancy, renal abscess, abdominal aortic aneurysm). It also has the advantage of lack of contrast exposure, short duration of testing, and ease of interpretation.

Contraindications to CT imaging are few. Obese patients may be unable to undergo CT scanning if their girth or weight is beyond the capacity of the scanner. CT also is not the preferred modality in pregnant patients because of radiation exposure to the fetus. In recent reports, CT scans underestimated the actual size of the stone by as much as 12% compared with the scout film from an IVP or KUB study. This limitation may adversely affect the management of patients with 5-mm stones, for example, in whom conservative therapy would be chosen on the basis of CT findings, although specific intervention would be more appropriate.

**Intravenous Pyelography.** IVP is an accurate imaging modality to detect renal stones, but it is seldom used since CT scanning and ultrasonography have become first-line imaging modalities. It is very sensitive, capable of establishing the diagnosis of calculous disease in 96% of cases, and it can quantify the presence and severity of obstruction. Contraindications to the use of urographic contrast media include renal insufficiency and previous reaction to radiocontrast material. The incidence of serious contrast reactions is extremely low and estimated to be 0.9 per 100,000. Its value also is limited by the complexity and length of time needed to perform the procedure, which can take as long as 2 hours.

**Ultrasonography.** Ultrasonography is safe and easily performed, but it is much less reliable than CT scanning for detecting small (less than 5 mm in diameter) ureteral and midureteral stones. Although only 37 to 64% sensitive for detecting calculi, ultrasound examination shows hydronephrosis with a sensitivity of 85 to 94% and a specificity of 100% (Fig. 97-5).
It is the study of choice for ruling out hydronephrosis in a pregnant patient with pyelonephritis, if obstructive urolithiasis is a concern, or in obese patients who cannot undergo CT scanning.\cite{46}

**Radiography of the Kidney, Ureter, and Bladder.** A kidney-ureter-bladder (KUB) film is the standard initial radiographic study done before injection of contrast medium during IVP. It is of limited usefulness on its own except as a progress film after CT has already identified a radiopaque stone. A KUB film is not reliable for diagnosing urolithiasis because it provides only presumptive evidence of calculi (less than 70% specificity), so it should be followed by a more definitive study. The most common radiographic densities seen on KUB films are phleboliths in the pelvic veins, which are spherical with a hollow (lucent) center, whereas calculi usually are irregularly shaped and solid. Calcified mesenteric lymph nodes also may add confusion, although unlike phleboliths, these densities commonly change position on subsequent films.

Most calculi (90%) are radiopaque, including calculi composed of calcium oxalate, cystine, calcium phosphate, or magnesium-ammonium-phosphate (Figs. 97-6 and 97-7). Uric acid stones, blood clots, and sloughed papillae are seen as “negative” shadow on radiographs. The most commonly overlooked calculi lie in the region over the sacrum, where small stones often are obscured by this bony density.

**Differential Considerations**

A number of significant clinical entities can produce flank pain (Box 97-3) and should be considered in patients with symptoms suggestive of renal colic. Such conditions include abdominal aortic aneurysm, pyelonephritis, carcinoma, renal tuberculosis, papillary necrosis, and vascular compromise.

Acute pyelonephritis can cause severe renal pain. Urinalysis will aid in the differential diagnosis by demonstrating pyuria and bacteriuria. However, infection also can occur concomitantly with an obstructive stone. This combination constitutes a true urologic emergency and requires imaging (renal CT, ultrasonography, IVP) to rule out hydronephrosis, which may warrant immediate urologic intervention (placement of ureteral stents).

Renal carcinoma also may produce flank pain, especially if hemorrhage has occurred within the tumor. An abdominal flat-plate radiograph (a KUB film) may demonstrate calcifications overlying the renal shadow, which often are seen in renal neoplasms. IVP may suggest the diagnosis, but CT scan is the best imaging modality.

Papillary necrosis may cause renal colic as a result of passage of sloughed papillae down the ureter. It most is often seen in
diabetics and in patients with a history of acute or chronic UTI. Sloughed papillae may be visualized on renal imaging and can be mistaken for an obstructive stone.

Renal pain, either colicky or noncolicky, also is produced by acute vascular compromise of a kidney. The pain of renal infarction is severe and occasionally associated with microscopic or gross hematuria. The acute vascular changes may be secondary to renal artery embolism, renal vein thrombosis, dissection of the renal artery, rupture of a renal artery aneurysm, aortic dissection, or abdominal aortic aneurysm. If a vascular etiology is suspected, a contrast-enhanced CT scan or an angiogram should be performed. The most common of these relatively rare processes is renal artery embolism, which most often is of cardiac origin (as with atrial fibrillation, subacute bacterial endocarditis, or mural thrombus). An immediate angiogram is indicated because early diagnosis allows possible salvage of the ischemic kidney. Most renal artery aneurysms are small and seldom produce clinical manifestations. Dissection or rupture of a renal artery aneurysm is rare and causes shock and flank pain. Renal vein thrombosis often demonstrates microscopic hematuria and proteinuria. The KUB film may show an increased renal shadow, and in the early stages, contrast studies show decreased function of the affected kidney. Predisposing factors for renal vein thrombosis include nephrotic syndrome, malignancies, and pregnancy.

A renal or perinephric abscess may cause flank pain, fever, and a palpable mass. Ultrasonography or a CT scan should be performed. A chest radiograph may demonstrate a pleural effusion or elevation of the diaphragm. Both renal and perinephric abscesses require hospitalization for drainage, intravenous fluids, antibiotics, and determination of the underlying cause.

Management

General Approach. Patients with renal stones generally are in severe pain and are unable to find a comfortable position. Often, the history and physical examination, combined with the finding of hematuria, allow a presumptive diagnosis to be made and therapy to be initiated. The first priority is adequate pain control. Nonsteroidal anti-inflammatory drugs (NSAIDs) are first-line agents, but parenteral administration often is necessary because of vomiting. Intravenous ketorolac (Toradol) provides rapid effective analgesia with minimal side effects. In addition to their analgesic effects, NSAIDs decrease the pain of renal colic by decreasing ureterospasm and also reduce renal capsular pressure by diminishing the glomerular filtration rate in the obstructed kidney. Accordingly, caution is advised with use of these agents in patients with underlying renal insufficiency or peptic ulcer disease. An antiemetic may be useful if the patient complains of nausea, and intravenous fluids should be given to the vomiting patient who is unable to tolerate liquids and who is likely to undergo an imaging procedure.

Narcotics (morphine sulfate, meperidine, or hydromorphone) also are very effective in providing rapid analgesia, faster than NSAIDs. However, they carry a higher incidence of side effects than that noted with NSAIDs. The combination of NSAIDS and opiates is an acceptable approach that may
Figure 97-6. In a near-term pregnant woman with an obstructed left kidney, intravenous pyelography demonstrates a delayed nephrogram. The right kidney has physiologic hydronephrosis from ureteral compression by the fetal head.

Figure 97-7. In a near-term pregnant woman with an obstructed left kidney, intravenous pyelography demonstrates a delayed nephrogram. The right kidney has physiologic hydronephrosis from ureteral compression by the fetal head.
Most patients with nephrolithiasis may be safely discharged to home from the ED. Current guidelines recommend urologic intervention in patients with symptoms persisting for longer than 2 months. The patient should be instructed to drink a moderate amount of fluids, to take analgesics as needed for pain, and to engage in activity as tolerated.

Medical expulsive therapy is another important aspect in the management of ureteral stones. Because ureteral smooth muscle contraction is mediated by intracellular calcium and by the autonomic nervous system, α1-antagonists and calcium channel blockers facilitate distal stone expulsion and decrease the time to spontaneous stone passage. These agents work by blocking ureteral smooth muscle contraction and improving antegrade stone movement. Both types of medications have been shown to assist in stone passage. Such therapy tends to be most efficacious with stones less than 5 mm in diameter located in the distal ureter. No published studies have addressed the usefulness of medical expulsion therapy with stones larger than 6 mm in the absence of shockwave lithotripsy, and no studies have compared the efficacy of α1-antagonists and calcium channel blockers. The most common medication prescribed to facilitate stone passage is either tamsulosin or nifedipine, although other drugs in the same class seem to be equally effective. Proper discharge instructions should include work and driving restrictions for patients taking narcotics. In addition, patients should be instructed to strain all urine with a strainer manufactured for this purpose. If such a device is not available, patients may simply void into a glass jar; the calculus should be visible at the bottom. The stone should be saved and submitted to the urologist for analysis. Patients should be instructed to return to the ED immediately for intractable or severe pain, persistent nausea and vomiting, fever or chills, or difficulty voiding. Finally, an outpatient urologic evaluation should be scheduled.

**Indications for Hospital Admission.** Hospital admission should be sought for patients who are severely dehydrated, are experiencing unremitting pain or vomiting, or have an underlying urinary infection (Box 97-4). Sepsis and renal damage are risks in the presence of obstruction and infection, so admission to the hospital floor is inadequate. These patients require immediate urologic consultation to evaluate the need for drainage and for relief of the obstruction (usually ureteral stenting). If signs of sepsis (tachycardia, fever, hypotension, shock) are present, antibiotics and fluid resuscitation should be administered while awaiting urologic evaluation. Immediate operative intervention may be indicated to provide drainage and relieve the obstruction.

A patient who returns to the ED with persistent colic may not need a second imaging study if the stone was identified previously. In such cases, a KUB film may localize the stone. An intervention by the urologist may be necessary if the stone has not progressed along the genitourinary tract. Several interventional strategies are available to the urologist for the management of stones that do not pass spontaneously. Optimal therapy depends on the size, location, and composition of the stone. Extracorporeal shock wave lithotripsy (ECSWL) has proved to be effective for stones located in the kidney, with a greater than 85% clearance rate. Upper ureteral stones also may be cleared with a high success rate when ECSWL is performed after ureteroscopic manipulation of the stone to a more proximal position. Percutaneous nephrolithotomy, which establishes a tract from the skin to the collecting system, is used for stones too large or hard for ECSWL by removing them directly from the renal pelvis. Stones unresponsive or unlikely to respond to other techniques may require surgical removal.

### BLADDER (VESICAL) CALCULUS

Although calculi generally form in the kidneys, they also may originate in the bladder. Bladder stones constitute a different entity from that of renal stones. In the United States, bladder stones occur almost exclusively in elderly men, often as a complication of other urologic disease. The most common cause is infection of residual bladder urine with urea-splitting organisms. The other common cause of vesical stones is an indwelling catheter. Disorders predisposing to the formation of bladder stones include bladder neck obstruction (usually secondary to prostatic hyperplasia), neurogenic bladder, vesical diverticula, damage from irradiation, and schistosomiasis.

The presenting manifestations most often are pain on voiding and hematuria. The patient may complain of a sudden interruption of the urinary stream, which strongly suggests a vesical stone that intermittently obstructs the bladder outlet. Frequency, urgency, and dysuria are described by up to 50% of patients, and UTI is common. Physical examination is rarely rewarding because signs may be minimal. Rectal examination may reveal an enlarged prostate or a prostatic malignancy. Poor sphincter tone may suggest a neurogenic bladder. Urinalysis generally reveals pyuria, bacteriuria, and hematuria. Plain radiographs of the pelvis reveal a bladder stone in 50% of cases. Contrast scans may demonstrate obstructive changes in the upper tracts or bladder diverticula. Ultrasonography also is useful in the diagnosis of bladder stones.

### ACUTE SCROTAL PAIN

#### Perspective

Several unique disorders encountered in the ED setting produce scrotal pain. It is crucial to determine the exact etiologic disorder in such cases because testicular torsion, a common cause of scrotal pain, represents a surgical emergency, mandating rapid recognition and treatment. Other causes of scrotal pain require less invasive and time-dependent therapies, such as antibiotics for epididymitis and observation for benign masses or torsion of the appendix of the testes.

#### Principles of Disease

**Anatomy.** Knowledge of testicular landmarks is essential for examination of the patient with an acute scrotal mass.
On examination of the testis, any tenderness is often higher than the right, because its blood flow empties into the relatively smaller, high-pressure renal vein, whereas the right drains into the relatively larger, low-pressure vena cava. A normal testis is found in the vertical axis with a slight forward tilt, and the epididymis is above the superior pole in the posterolateral position.

Physical Examination. On examination of the testis, any tenderness to palpation, discrepancies in size, loss of testicular landmarks, or discoloration should be noted. The epididymis is located posterolateral to the testis and should be nontender to rotation. Torsion in neonates often is congenital and by the time the condition is noted at birth, the testicle is not salvageable.60

Differential Considerations

Acute scrotal pain can arise with testicular torsion, epididymitis, torsion of the appendix of the testis, testicular tumor, or a hernia. Testicular torsion is the most important etiologic disorder to be excluded because any delay in treatment of this condition is associated with increased risk of testicular loss and infertility.

Specific Disorders

Testicular Torsion

Perspective. Testicular torsion is identified in approximately 16 to 42% of patients coming to the ED with scrotal pain.54 56 It is the most common cause of the acute scrotum in prepubertal boys, with a peak incidence in the first year of life.54 It also has a second peak incidence at puberty, when the rapid increase in testicular volume predisposes the testis to torsion. It also can occur in adulthood, as evidenced by a retrospective review of data for 44 patients with torsion, of which 17 were older than 21 years of age.58 Factors that increase the likelihood of torsion include horizontal lie of the testis, increased length of the spermatic cord in the scrotum, and a history of cryptorchidism.59

Principles of Disease. With torsion, an extravaginal or intravaginal defect of the testis leads to twisting of the spermatic cord and decreased blood supply to the testicle. The cremasteric muscle surrounds the spermatic cord, and in the normal testicle, the testicle does not rotate when the cremasteric muscle contracts. In patients with torsion, however, the anatomic defect allows the tunica vaginalis to insert higher on the testicle, where it encircles the epididymis and distal spermatic cord. When the cremasteric muscle contracts in this abnormal scrotum, there is more room for the testicle to move, and it twists around the spermatic cord. Its movement resembles the ringing of the clapper in a bell—hence the description of a “bell clapper” deformity. By contrast, extravaginal defects occur almost exclusively in neonates and arise because the testicle lies outside of the tunica vaginalis, where it is prone to rotation. Torsion in neonates often is congenital and by the time the condition is noted at birth, the testicle is not salvageable.60

Testicular trauma also has been associated with torsion and has been noted in the literature to occur after motor vehicle collisions, straddle injuries, and athletic injuries. In these instances, the symptoms of torsion often are misattributed to the trauma itself, so the diagnosis is delayed. As a result, testicular salvage rates are only 40% after groin trauma.61 In order to prevent loss of the testicle, scrotal pain persisting for an hour after any traumatic injury should raise suspicion for concomitant torsion of the testis.

As the testicle twists around the spermatic cord in torsion, it initially hinders venous return. Persistent torsion produces arterial obstruction, leading to ischemia and eventual necrosis of the testicle. With increasing degrees of rotation of the cord, ischemia increases, and infarction of the testicle occurs much more rapidly. Unfortunately, no clinical method has been devised for determining the extent of rotation of the testicle.
and the resultant likelihood of rapid ischemia. The duration of vascular obstruction also affects the ability to salvage the testicle; torsion recognized within 6 hours is associated with testicular salvage rates of 80 to 100%, whereas persistence of symptoms for 24 hours or longer is associated with nearly universal loss of the testicle.62

Clinical Features. Patients typically complain of sudden onset of scrotal pain that awakens them from sleep or develops several hours after physical activity. The pain arises in the scrotum, lower abdomen, or inguinal area. Patients tend to seek medical attention at approximately 9.5 hours into their disease course, earlier than patients with alternate causes for an acute scrotum.63 Up to 29% of patients describe similar pain in the past, due to previous intermittent torsion in a predisposed testicle.64 Patients often complain of nausea and vomiting, although no historical factors, including nausea, vomiting, fever, urinary symptoms, and a history of trauma, have been found to differentiate torsion from other causative disorders (Table 97-6).

The physical exam is much more reliable than the history in determining the presence of testicular torsion. The most common finding is loss of the cremasteric reflex, observed in nearly 100% of patients older than 30 months of age with torsion.57 In a retrospective review of 245 patients with acute scrotal swelling, none of the patients with a cremasteric reflex had torsion.65 This sign also is relatively specific, because most patients with other causes of scrotal pain have an intact cremasteric reflex. In addition, patients with torsion frequently have a tender, firm testicle that can be higher than the contralateral testicle, owing to shortening of the spermatic cord as it twists. This twisting also can leave the testicle in the transverse position and displace the epididymis from its usual location along the posterior aspect of the scrotum. Often the patient’s scrotum is so swollen and tender that a complete physical exam is impossible. After 24 hours, the physical exam is not particularly helpful, because many of the aforementioned findings are no longer present.66 Despite the limitations of the physical exam, any patient presenting with acute onset of scrotal pain and any of the aforementioned physical findings should be considered to have torsion until proven otherwise.

Diagnostic Strategies. In patients in whom the history and physical findings strongly suggest torsion, urgent surgical consultation is warranted. If the diagnosis is equivocal, adjunctive tests can be performed to determine the cause of the pain. Although urinalysis results suggestive of infection are consistent with epididymitis, such findings also may be noted in patients with torsion and concomitant UTI. Similarly, a complete blood

Note: No single finding in patients with an acute scrotum can reliably differentiate torsion from other causative disorders. When torsion is a diagnostic possibility, prompt urology consultation is mandatory.

Figure 97-9. Doppler ultrasound image showing a testicle with no flow due to torsion. (From Blaivas M, Brannam L: Testicular ultrasound. In Rosen C, Wolfe R [eds]: Ultrasound in Emergency Medicine. Emerg Med Clin North Am 22:730, 2004 [Figure 7].)
are suggestive of torsion. Moreover, ultrasound examination should never delay evaluation by a urologist in any patient with probable torsion.

Radiosotope scanning has the advantage of improved sensitivity compared with ultrasonography, but it is a time-consuming test inappropriate for use in the ED.

**Management.** The first step in management of very strongly suspected testicular torsion is immediate consultation with a urologist. The longer the spermatic cord remains twisted, the lower the likelihood of testicular salvage. More than 90% of affected testicles can be saved within 6 hours of symptom onset, but by 24 hours, 100% are lost. After consultation, intravenous access is established and analgesia is provided either systemically or with a block of the spermatic cord. Manual detorsion should then be attempted as follows: The operator stands at the supine patient’s feet and then rotates the affected testicle away from the midline, as if turning the pages of a book. If this maneuver is successful, patients should report rapid reduction of symptoms. Most studies suggest this technique untwists approximately 26% of testicles under torsion; other studies, however, have achieved success rates as high as 80%. Some torsions involve rotation through 720 degrees, so continuing the untwisting maneuver past 360 degrees is recommended if no improvement is obtained initially, especially in cases in which torsion is strongly suspected. Regardless of the outcome with manual detorsion, patients still require surgical evaluation. In addition, evaluation by a urologist should never be delayed in order to perform this or any other test or maneuver.

**Disposition.** Rapid diagnosis of testicular torsion is essential and should be followed by emergent surgical scrotal exploration and bilateral orchidopexy, if necessary. Loss of the testicle most commonly is due to delay in seeking medical attention. However, almost 30% of cases of failed testicular salvage have been attributed to misdiagnosis, and another 13% to a delay in treatment after the proper diagnosis was established.

**Torsion of Appendages**

**Perspective.** A normal scrotum has several vestigial appendages that also can twist and become ischemic, with resultant scrotal pain. This process is most common between 7 and 14 years of age, with a mean age of 10 years. In retrospective analyses, torsion of an appendage rivals testicular torsion as the most common cause of the acute scrotum.

**Principles of Disease.** The appendix testis, a remnant of the paramesonephric duct, is present in 92% of patients. It is located on the superior aspect of the testicle between the testis and the epididymis. The appendix epididymis, a remnant of the mesonephric duct, is the second most common testicular appendage, found in approximately 23% of patients. It typically is located on the tip of the epididymis (Fig. 97-10). These appendages are prone to torsion owing to their pedunculated shape. After several days of ischemia due to torsion, they will undergo necrosis with eventual reabsorption. Their loss does not permanently affect fertility or have any impact on surrounding structures.

**Clinical Features.** As with testicular torsion, patients with torsion of an appendage complain of scrotal pain but report milder symptoms with a more gradual onset. These patients usually seek medical attention in the ED after 48 hours of symptoms. In contrast with testicular torsion, the pain often can be localized to one point on the testicle. These patients infrequently report nausea, vomiting, urinary symptoms, or previous episodes of similar pain.

On physical exam, twisting of the appendix testis leads to formation of a hard, tender, 2- to 3-mm nodule at the upper pole of the testicle. Unlike in testicular torsion, the entire testicle is not tender. The testicle also does not change in overall size, and the epididymis remains posterior. The cremaster reflex typically is intact. On transillumination, the ischemic appendage may appear as a blue dot. Although highly specific for torsion of the appendix, this sign is found in as few as 10% of patients. A reactive hydrocele can form during the course of disease, obscuring the physical findings with the twisted appendix.

**Diagnostic Strategies.** Urinalysis does not show evidence of infection. On ultrasound imaging, the appendix under torsion will appear hypoechoic. When the appendix then enlarges, the “Mickey Mouse” sign may be apparent on the transverse view, as a result of juxtaposition of the testicle, enlarged appendix, and epididymis. Color Doppler ultrasound examination and nuclear scintigraphy are useful imaging studies that show normal to increased blood flow to the involved appendage and symmetrical testicles.

**Differential Considerations.** Other diagnostic entities such as testicular torsion, epididymitis, and testicular tumor must be considered and excluded before a firm diagnosis of torsion of an appendage can be made.

**Management and Disposition.** If testicular torsion is ruled out, surgical excision of the appendix is rarely necessary. Treatment consists of scrotal support, ice, and NSAIDs. Resolution of symptoms can be expected within 7 to 10 days. Surgical excision is reserved for uncontrollable pain.

**Epididymitis**

**Perspective.** Epididymitis is the most common intrascrotal inflammatory disease. Nearly one half of the cases arise in young men, between the ages of 20 and 29 years, but the disease also has affected patients from 4 months to 76 years of age. If untreated, it can lead to orchitis, testicular abscess, and rarely sepsis.

**Principles of Disease.** The epididymis is a tightly coiled tubular area along the posterior aspect of the testes, where sperm mature before their transit to the vas deferens. It becomes infected when organisms travel retrograde from the vas deferens. With infection, the testis may become edematous secondary to passive congestion and inflammation. Resolution of
epididymitis typically concludes without sequelae, but peritubular fibrosis can occlude the ductules of the epididymis, leading to an increased risk of infertility.

Pathophysiology. The particular organisms involved in the infection depend on the sexual activity of the patient. Although the literature classically describes men younger than 35 years of age as prone to C. trachomatis and N. gonorrhoeae infections, all sexually active men, regardless of age, are at risk for epididymitis from these organisms. C. trachomatis is much more common, being identified in 47% of patients younger than 35 years, with N. gonorrhoeae seen in 20%. Ureaplasma also has been identified in patients with epididymitis, although whether it was the actual causative agent is unclear. In patients with syphilis, infection can spread to the epididymis during the secondary phase. In homosexual men who engage in anal intercourse, coliforms also can lead to sexually transmitted epididymitis.

In men older than 35 years of age, urinary tract pathogens become the predominant cause of epididymitis. E. coli is the most common, occurring in 32 to 55% in this age group. Pseudomonas aeruginosa and Proteus mirabilis also can infect the epididymis, and although much less common in the industrialized world, M. tuberculosis also has been implicated. In immunocompromised patients, fungal and other opportunistic infections have been reported.

Unlike younger patients, older men with epididymitis tend to have urinary tract abnormalities that predispose them to these infections of the epididymis. In one review, 56% of men older than 60 years of age with epididymitis had lower urinary tract obstruction. Older men also are more likely to have undergone recent genitourinary instrumentation, another risk factor for epididymitis. This includes hernia repair, which often can lead to iatrogenic infection of the nearby spermatic cord and epididymis. Acute or chronic prostatitis also may increase the risk of epididymitis. Finally, several authorities have suggested a possible association between indwelling catheters and epididymitis. Each of these factors renders older men prone to epididymitis after they are no longer sexually active.

Children also can have epididymitis, although it is a much less common cause of scrotal pain in this age group than testicular torsion. Children with epididymitis tend to have congenital genitourinary anomalies that predispose them to recurrent infection.

Amiodarone also has been implicated as a cause of epididymitis, with nearly 20 case reports in the literature. One study has suggested that amiodarone-induced epididymitis may be more common, arising in as many as 3 to 11% of patients receiving this agent. The effect is dose-dependent, typically occurring after at least 4 months of treatment and with doses of 400 mg or more per day. Amiodarone concentrates in the testicle, resulting in lymphocytic infiltration and epididymal fibrosis. Unlike with infectious epididymitis, patients do not have fever, pyuria, or leukocytosis.

Clinical Features. Patients with epididymitis experience scrotal pain of gradual onset, prompting them to come to the ED later in the clinical course than patients with torsion, whose symptoms tend to be more abrupt in onset. Initially, this pain may reside in the lower abdomen or flank, being due to inflammation of the vas deferens. In patients with STDs, urinary symptoms and urethral discharge are found in 10 to 30%. Nearly three fourths of patients report fever. In the early stages of the disease, tenderness is localized to the epididymis, but it quickly spreads to the adjacent testicle. Also, later in the course, the scrotum can become edematous, erythematous, and extremely tender. Although Prehn’s sign—decrease in pain with elevation of the scrotum—has been touted as indicative of epididymitis, it has low sensitivity and specificity. Similarly, only 10% of patients with epididymitis from sexually transmitted organisms have urethral discharge on exam. None of these historical factors or physical findings have been shown to reliably differentiate torsion from epididymitis.

Diagnostic Strategies. Urinalysis typically demonstrates evidence of infection, with the finding of pyuria in 50 to 93% of patients with epididymitis (defined as the presence of more than 4 leukocytes per high-power field). If patients are at risk for STD, a urethral swab or urine sample should be obtained to test for C. trachomatis and N. gonorrhoeae. Each of these tests has no role in the ED. Leukocytosis may be present but is a nonspecific finding and does not differentiate epididymitis from torsion.

In patients with a presentation equivocal for epididymitis and torsion, testicular ultrasound examination should be performed in the ED. With infection, the epididymis appears enlarged and hypoechoic. On color Doppler ultrasound images, the affected testicle will show increased vascularity. These findings are 70% sensitive and 88% specific for epididymitis and can help differentiate the condition from torsion.

Differential Considerations. Three intrascrotal processes are commonly confused with epididymitis: torsion, torsion of the testicular appendage, and tumor of the testicle. Epididymitis is the most common misdiagnosis in patients with torsion, and this error can lead to loss of the testicle.

Management. Empirical antibiotics should be selected in accordance with the patient’s age, sexual history, and any previous genitourinary instrumentation (Table 97-7). In patients with a suspected sexually acquired infection, ceftriaxone 250 mg IM or ciprofloxacin 400 mg PO should be given to treat possible N. gonorrhoeae infection. In conjunction, doxycycline 100 mg PO twice daily for 14 days should be started to treat C. trachomatis infection. Although this regimen has never been
studied in patients with chlamydial epididymitis, it is presumed to be more successful than the single-dose azithromycin that is used for noncomplicated urethritis. Treatment of sexual partners should be arranged even if the patient’s urine culture demonstrates no growth, because in one study, 80% of female partners of men with epididymitis were found to harbor C. trachomatis infection, including partners of men with negative urine culture results.

In patients with infection by urinary tract pathogens, ciprofloxacin 500 mg PO twice daily has been shown to be the most successful regimen, with 80% of patients improving after 14 days of treatment. Ofloxacin 200 mg PO twice daily for 14 days is an alternative that also will cover sexually transmitted organisms and therefore is the ideal treatment when it is unclear if a patient has sexually acquired or urinary tract pathogens. Treatment can later be adjusted in accordance with the results of the patient’s urine culture. In addition to appropriate antibiotics, bed rest, scrotal support, analgesics, sitz baths, and ice packs may be beneficial. A urologist can block the spermatic cord with bupivacaine to provide pain relief. This maneuver also appears to hasten the healing process, perhaps by increasing blood flow to the spermatic cord that was anesthetized. On discharge, the patient should be referred to a urologist for follow-up evaluation within 1 week.

Typically, symptoms resolve in 2 weeks in patients with sexually acquired disease and in 4 weeks in patients with urinary tract pathogens. Complications are more common in older men, occurring in 39% of patients, and include intratesticular and epididymal abscess, testicular infarction, and late testicular atrophy. In younger patients, infection often reduces spermatogenesis, but the long-term effect on fertility is unclear.

Dispositional Features. Patients with systemic signs of toxicity (fever, chills, nausea, vomiting) or complications of acute epididymitis should be hospitalized and treated with parenteral antibiotics. Patients discharged from the ED should be reassessed within 1 week to ensure that their symptoms are resolving. Spread of infection, continued scrotal edema, ongoing testicular pain, and scrotal wall fixation are indications that outpatient management has failed, and hospitalization and emergent urologic evaluation are required to rule out an alternate diagnosis such as testicular torsion or scrotal abscess.

Testicular Tumors

Perspective. Tumor of the testis is the most common malignancy in young men but accounts for only 1% of all cancers in men. These tumors are more common in infertile patients and whites. They also occur with increased frequency in the non-descended and descended testicles of patients with cryptorchidism. A number of simplified classification systems have been proposed for categorizing the different types of testicular tumors. Approximately 95% of tumors are germ cell tumors, with half of these being seminomas and the other half being mixed types, including teratomas, choriocarcinomas, and yolk sac tumors. The other 5% of testicular tumors are sex cord stromal tumors. The disease course will depend on the type of tumor present as well as the age of the patient.

Clinical Features. Unlike in torsion and epididymitis, patients with tumor typically present with a painless scrotal mass. When pain develops, it most often is due to acute hemorrhage within the tumor pushing against the nonpliable tunica albuginea. Presence of pain should be considered unusual with testicular tumor, and in such cases, torsion and epididymitis should be ruled out before a diagnosis of malignancy is considered. Patients with tumor also can present with symptoms related to metastases from a previously undiagnosed testicular cancer; 15% of patients have metastases to regional lymph nodes at the time of diagnosis and 5% have metastases to the abdomen or pelvis.

Diagnostic Strategies. All patients with a scrotal mass should undergo a scrotal ultrasound examination. This study can reveal a concomitant hydrocele or a homogeneous hypoechoic lesion. Although helpful for staging purposes, CT scans of the chest and abdomen are necessary in the ED only if the patient has complaints related to these parts of the body. Urinalysis findings typically are normal.

Management. Suspicion of a testicular tumor is an indication for urgent referral to a urologist, because radical orchiectomy with high ligation of the spermatic cord may be required. The radiosensitive nature of seminomas renders the combined treatment of orchiectomy and radiation therapy highly successful for early-stage disease. The ultimate treatment strategy, however, should be determined by a urologist. Any patient with systemic symptoms should be admitted to the hospital.

Orchitis

Perspective. Orchitis is a rare acute infection of the testis. It is most common in prepubertal boys, with viral infections such as mumps causing a majority of cases. Orchitis develops in approximately 20% of prepubertal boys with mumps but in almost no postpubertal males with mumps. It tends to arise several days after the onset of parotitis. Owing to the testes’ relatively high threshold of resistance to infection, bacterial orchitis more commonly results from local bacterial spread from the epididymis. The most frequent bacterial pathogens are N. gonorrhoeae, C. trachomatis, E. coli, Klebsiella, and P. aeruginosa. These organisms tend to infect postpubertal males and men older than 50 years of age with benign prostatic hypertrophy (BPH).

Clinical Features. Patients with bacterial orchitis present with fever and scrotal pain. They often have constitutional signs and symptoms including nausea, vomiting, myalgias, and malaise. The affected testicle (the disease is unilateral in 70% of patients) and scrotum are swollen, tender, and erythema-
tous. A patient with viral orchitis has testicular pain and swelling that commonly begins 4 to 6 days after the onset of parotitis, although it can develop in the absence of parotitis. The clinical course varies, but resolution generally occurs in 4 to 5 days. More than 50% of testes involved with mumps orchitis suffer from atrophy; however, this seldom results in infertility.

**Diagnostic Strategies.** As with all causes of scrotal pain, the first priority is to exclude testicular torsion. If the patient clearly has mumps orchitis based on the clinical presentation and a history of preceding parotitis, then no other tests are necessary. For all other patients, urinalysis and urine culture should be performed. Patients in whom the diagnosis is unclear also should undergo color Doppler ultrasound examination to evaluate for torsion or concomitant epidermiditis.

**Management.** In sexually active patients, ceftriaxone and doxycycline should be used as in epididymitis to cover *N. gonorrhoeae* and *C. trachomatis*. In older patients, fluorquinolones provide the best coverage of gram-negative organisms. Treatment of viral orchitis is supportive only. All patients should receive local scrotal care, as described for epididymitis. Patients with marked pain, high fever, or constitutional symptoms merit hospitalization and parenteral antibiotics.

**Inguinal Hernia and Acute Hydrocele**

Both inguinal hernia and acute hydrocele are reasonable considerations in the differential diagnosis of an acute scrotal mass. However, both of these clinical entities should be readily identified by careful physical examination.

### ACUTE URINARY RETENTION

#### Perspective

Acute urinary retention (AUR) is the sudden inability to pass urine voluntarily. In contrast with patients with anuria, in which the kidneys fail to produce urine, patients with AUR have normal renal function but cannot pass urine and typically have a distended bladder. The risk of AUR increases with age: 10% of men in their 70s and 33% of men in their 80s experience AUR at some point. The retention most commonly is secondary to an obstructive lesion but also can be the presenting manifestation of other pathologic processes (Box 97-5). For example, in women it often develops from infrequent voiding leading to an atonic bladder. In younger patients, it often is suggestive of a serious underlying neurologic disease.

The most common cause of AUR seen in the ED is obstruction of the urinary tract distal to the bladder. In men, BPH is the typical precipitant, causing AUR in 53% of patients.\(^9\) Enlargement of the prostate coupled with constriction of the prostatic urethra from heightened α-adrenergic tone obstructs urinary output.\(^9\) Prostate cancer also can block the urethra by means of similar mechanisms, and urinary retention develops in 70% of patients with this tumor. Approximately 25% of men presenting to the ED with AUR have prostate cancer, and often this cancer diagnosis was not known beforehand.\(^9\) Strictures of the urethra can arise after trauma from manipulation with a Foley catheter, cystoscopy, previous infections, or radiation therapy. Such strictures may then lead to obstructed urinary outflow. Other, less common obstructive causes of AUR include phimosis (inability to retract the foreskin over the glans penis) and paraphimosis (inability to reduce the foreskin over an edematous glans).

In women, the most frequent causes of obstructive AUR are pelvic masses and prolapse of pelvic organs such as bladder, rectum, or uterus. These structures compress the urethra, thereby creating AUR. In both sexes, bladder neoplasms, fecal impaction, GI masses, foreign bodies, or stones can block urine outflow. Finally, congenital posterior urethral valves are the most common source of AUR in children.

Infection also can cause AUR and must be considered in the differential diagnosis, because treatment of the condition through placement of a catheter will correct the retention but not the underlying infection. The most common infectious etiologic disorder is acute prostatitis, which usually is due to infection of the prostate by *E. coli* or *P. mirabilis*. The resulting edema causes AUR, particularly in the setting of BPH or other underlying prostatic disease. Similarly, urethritis from a UTI or sexually transmitted infection can obstruct the urethra, and in women, vulvaginitis also can produce enough urethral edema to create AUR. In Elsberg syndrome, genital herpes involving the sacral nerves leads to AUR.\(^9\) Finally, in pediatric
Pharmacologic agents have been associated with AUR. Anticholinergic agents inhibit detrusor muscle contraction, whereas sympathomimetic agents increase α-adrenergic tone in the prostate. In addition, NSAIDs may inhibit prostaglandin-mediated detrusor muscle contraction, leading to a twofold increase in risk of AUR in men taking these drugs.93

Although less common in older patients, neurogenic causes of AUR constitute an important etiologic category. Upper motor neuron lesions create bladder spasticity through a deficit above the micturition center in the sacral cord. They result from spinal cord and cortical lesions due to multiple sclerosis, trauma, Parkinson’s disease, stroke, or neoplasms. Lower motor neuron deficits produce bladder flaccidity with lesions below S1. Such lesions typically are associated with spinal cord tumors, epidural abscesses, spinal trauma, Guillain-Barré syndrome, tabes dorsalis, and multiple sclerosis. Peripheral nerve lesions also can cause AUR. Diabetic peripheral neuropathy is the most commonly encountered peripheral lesion and occurs in 45% of patients with diabetes mellitus.94

Numerous alternate causes for AUR are recognized, as listed in Box 97-5. They include intervertebral disk herniation, recent surgery, and psychogenic causes. In the ED, these are encountered much less frequently than the aforementioned disorders. Psychogenic urinary retention also is rare and should be a diagnosis of exclusion made only after appropriate studies of bladder function have been performed by a urologist.

Clinical Features

Although the potential causes of AUR are many, the history and physical exam can considerably narrow the scope of the differential diagnosis (Table 97-8). Patients with AUR present in pain with a distended bladder that is tender to palpation (Box 97-6). With lesions proximal to the bladder, patients typically note pain in the flank, whereas lesions distal to the bladder can produce pain radiating to the scrotum or labia. By contrast, with slowly developing or chronic obstructions, patients typically are older, with multiple comorbid conditions, and they present with overflow incontinence and report little to no pain.

When obstruction is the cause of AUR, the patient often will recall multiple previous episodes of urinary retention. In addition to this history, patients with BPH will report frequency, urgency, hesitancy, nocturia, difficulty initiating the urinary stream, decreased force of the stream, a sensation of incomplete voiding, and terminal dribbling. The prostate is enlarged, firm, and non-nodular. Normal findings on the prostate exam do not exclude BPH. Patients with prostate cancer can have similar symptoms, but these often are accompanied by weight loss, bone pain, and other constitutional signs and symptoms. These patients generally will have an enlarged, nodular prostate. Examination of the penis also is crucial in men, because phimosis and paraphimosis will reveal edema of the penis with a nonretractable foreskin. In women with obstruction, pelvic pain and pressure are symptoms commonly associated with AUR. A prolapsed bladder, rectum, or uterus and enlarged ovaries or uterus can be identified on pelvic examination.

Patients with an infectious cause for their symptoms often complain of dysuria, frequency, urgency, hematuria, fever, chills, and low back pain. In acute prostatitis, these symptoms can be associated with penile discharge and a tender, warm, and boggy prostate. Despite the obstruction, the patient may nevertheless be able to void small amounts of urine. In vulvovaginitis and urethritis, presenting complaints also may include discharge and pruritus.

Patients with a neurogenic cause for their AUR may already have a history of neurologic disease. They require a thorough neurologic examination, focusing on strength, sensation, and reflexes in the lower extremities, for which innervation is similar to that of the bladder. The status of the bulbocavernous reflex, anal reflex, sphincter tone, and perineal sensory should be assessed.

Diagnostic Strategies

The only two mandatory tests in the ED for AUR are placement of a Foley catheter and a urinalysis. The urinalysis can reveal infection, whereas presence of hematuria suggests infection, tumor, or calculi. Patients with hematuria require follow-up, because the bleeding can arise from obstructive obstruction alone or may have other, more serious causes such as bladder cancer. A basic chemistry panel for assessment of renal function should be obtained only when renal damage or hydronephrosis is a concern.

Imaging studies are indicated when patients have evidence of concomitant infection or neurologic deficits. Renal and bladder ultrasound studies provide visualization of any obstruction, hydronephrosis, or other causes of upper urinary tract disease. Pelvic ultrasound examination and CT scan evaluate for masses or malignancy causing obstruction. Magnetic resonance imaging of the spine evaluates for disk herniation, cord compression, and cauda equine syndrome. Cystoscopy and retrograde cystourethrogram can depict problems in the lower urinary tract and are usually performed as outpatient procedures.

Several other tests described in the literature provide little benefit in the ED management of patients with AUR. Prostate-specific antigen (PSA) levels frequently are elevated in the setting of AUR, so a PSA assay will not help in differentiating cancer from other causes of retention. Similarly, alternate imaging modalities have rendered IVP unhelpful in the ED.

Management

Immediate placement of a 14F to 18F Foley catheter should provide decompression of the bladder. If this fails, placement of an elbowed catheter (Coude catheter) should
be attempted; its curved tip allows it to pass more easily across any obstruction. If both of these techniques prove to be unsuccessful, a urologist should be consulted unless the ED personnel are well versed in the use of filiforms, followers, and metal sounds, because such instrumentation without the requisite degree of skill may result in serious tissue damage.

When immediate bladder decompression is required and a urologist is not available or major urethral trauma is present, suprapubic bladder drainage should be performed. Using ultrasound guidance and sterile technique, a 22-gauge spinal needle should be inserted two fingerbreadths above the symphysis pubis in the midline and directed toward the anus. The needle is advanced until urine is aspirated. Return of air suggests that the needle is in the bowel, and the needle should be retracted and moved more cephalad. Once the bladder is located, a 1-cm skin incision is made, and a suprapubic trocar is inserted into the bladder. The catheter is advanced over the trocar, which is then removed. If these devices are not available, a central venous set may be used, with the 12- to 18-inch tubing inserted into the bladder before the needle is withdrawn (Fig. 97-12).

### Complications

Catheterization has been associated with urethritis, cystitis, prostatitis, bacteremia, and sepsis. These infections are most common in patients with indwelling catheters and elderly debilitated female patients. Placement of a catheter has also been reported to cause postobstructive diuresis and hematuria. Such problems are believed to be related to rapid bladder decompression, so historically, gradual decompression has been recommended to prevent complications such as hematuria, hypotension, and postobstructive diuresis. Although hematuria occurs in 2 to 16% of patients after rapid bladder emptying, no major consequences from this bleeding have been documented. Similarly, postobstructive diuresis can cause transient hypotension, but it is responsive to fluid administration. The side effects of rapid bladder decompression are rare; therefore, all patients with AUR should undergo rapid, complete decompression of the bladder.

![Figure 97-12. Cystostomy tube placement.](image)
Disposition

After bladder drainage, healthy and reliable patients can be safely discharged with an indwelling catheter. Follow-up with a urologist should be arranged before the patient leaves. Patients with concomitant infection, significant comorbid illnesses, impaired renal function, neurologic deficits, or complications from catheterization require emergent urology consultation and probably admission.

At hospital discharge, the catheter should remain in place and the patient educated about catheter management. Prophylactic antibiotic therapy should not be initiated, because although bacteriuria often develops in patients with indwelling catheters, it typically is asymptomatic. Antibiotics only promote resistance among these organisms. Although the catheter is an inconvenience for the patient and chronic use has been associated with UTI, trauma, stones, and urethral strictures, early removal of the catheter also is associated with heightened risk for recurrence of AUR.96 In patients with suspected BPH, if the bladder was drained and a catheter was not left in place, recurrent AUR developed in 70%.97 In patients in whom the catheter remained in place for 3 days, AUR developed in 49%, and when the catheter was in place for 7 days, AUR recurred in only 38% of patients.98 As indicated by these results, the catheter should remain in place until the patient visits the urologist as an outpatient.

Studies also suggest that initiation of an α-adrenergic blocker, such as tamsulosin, at the time of catheter insertion improves the likelihood of spontaneous voiding after catheter removal.99 These medications should be provided only after consultation with the urologist or primary care physician, because they increase the risk of orthostatic hypotension, particularly in the elderly.91

HEMURIA

Perspective

Although hematuria is commonly encountered in the ED, the specific underlying disorder often is elusive. Most cases seen in the ED are asymptomatic microscopic hematuria, an incidental finding noted on routine examination through microscopic or dipstick analysis of the urine. The bleeding typically is transient and not indicative of serious underlying pathology. After an uneventful workup, patients often are referred for outpatient evaluation; however, the cause of the hematuria remains unknown in 61% of patients evaluated with lab and imaging studies.100 Less commonly, patients come to the ED complaining of gross blood in their urine. Unlike microscopic hematuria, gross blood in the urine often is the presenting symptom of an underlying malignancy. The risk of malignancy is greater in older patients; in those older than 60 years, gross hematuria has a positive predictive value for malignancy of 22.1% in men and 8.3% in women.101 Regardless of age or visibility of blood in the urine, patients with hematuria require evaluation in the ED to rule out life-threatening diagnoses such as malignancy and abdominal aortic aneurysm.

Principles of Disease

Blood in the urine can be gross or microscopic. As little as 1 mL of whole blood in 1 L of urine can produce gross hematuria, turning the urine red. Multiple other substances and reactions can turn the urine red, and centrifugation of the urine and microscopic analysis differentiate these false positives from true hematuria. After centrifugation, the red color persists only in the urine sediment with hematuria. By contrast, a red supernatant appears bloody but contains no RBCs on microscopic analysis, and the cause typically is a benign condition (Box 97-7). A red supernatant also may result from pathologic conditions such as myoglobinuria and hemoglobinuria. The supernatant will then contain heme in addition to a red coloring agent.

**Microscopic hematuria** is the presence of more than 3 to 4 RBCs per high-power field in clear urine. The particular cutoff for number of RBCs per high-power field used is arbitrary. Lower numbers of RBCs per high-power field decrease specificity but increase sensitivity, because significant disease can occur with as little as 1 RBC per high-power field. Urine dipstick increases sensitivity to 91 to 100% for the presence of blood, detecting 1 or 2 RBCs per high-power field. However, it is less specific, with false positives occurring when sperm are present and with alkaline or extremely concentrated urine.102,103 Accordingly, a positive result on urine dipstick testing should be confirmed with microscopic analysis.

Bleeding from anywhere along the genitourinary tract can produce hematuria. In both the upper and lower portions of the urinary tract, infection, trauma, and renal calculi are the most common etiologic disorders. Patients also can have more serious causes of hematuria such as malignancy or vascular lesions (e.g., abdominal aortic aneurysm), and these diagnoses must be excluded. Age older than 40 years, cigarette smoking, occupational exposure to chemicals such as aniline dye and benzidine, and excess use of analgesics increase the risk of malignancy. When another cause for the hematuria, such as UTI or stone, is identified in the ED, close follow-up is still necessary, because patients with these risk factors often prove to have an underlying malignancy.104 In the upper urinary tract, the glomerulus is the most frequent source of bleeding, which may result from glomerulonephritis, immunoglobulin A (IgA) nephropathy, or nephritis. The common causes of hematuria are further divided by patient age and gender in Box 97-8.

Occasionally, hematuria also has been attributed to warfarin usage, BPH, and exercise. Supratherapeutic anticoagulant therapy can lead to blood in the urine, but therapeutic anticoagulation does not produce hematuria. The incidence of hematuria was not significantly different between controls and 243 patients followed prospectively while receiving warfarin.105 Similarly, BPH can lead to increased vascularity of the prostate but does not increase the risk of hematuria. High-intensity exercise also can produce hematuria. This bleeding typically is transient and clinically inconsequential. However, a concomitant genitourinary tract lesion can be present, particularly if the bleeding persists for more than 72 hours after exercise.106 Because warfarin use, BPH, and exercise do not directly cause persistent hematuria, patients in

whom these factors are present require evaluation identical to that for other patients.

**Clinical Features**

The timing and appearance of the blood in the urine can help narrow the scope of the differential diagnosis (Table 97-9). Repeated episodes of bleeding during and after menstruation in women suggests endometriosis of the urinary tract. Gross hematuria suggests lesions in the lower urinary tract. Passage of clots indicates a source below the kidney. Finally, passage of a large amount of congealed blood in the urine suggests malignancy of the kidney.

Several other historical factors also are associated with particular causes of hematuria (Box 97-9). A careful history will identify a benign cause for hematuria, such as menstruation, recent heavy exercise, or sexual activity, as well as the use of agents that can produce red urine without blood (see Box 97-7). Patients may report frequency, urgency, and dysuria in the setting of infection. They may complain of flank pain with urolithiasis or pyelonephritis. IgA nephropathy arises days after a viral respiratory infection, whereas poststreptococcal glomerulonephritis develops in children 1 to 2 weeks after skin or throat infections.

The physical exam is crucial in establishing the diagnosis. Hypertension occurs with glomerulosclerosis and, in the setting of peripheral edema, suggests nephrotic syndrome. Atrial fibrillation increases the likelihood of embolic disease and renal infarction. An abdominal bruit may be due to an arteriovenous fistula, whereas a palpable abdominal mass may represent an abdominal aortic aneurysm. Flank pain and tenderness can arise with pyelonephritis or nephrolithiasis. The external genital exam can show evidence of trauma or a tumor.

**Diagnostic Strategies**

A clean-catch or catheterized urine specimen should be obtained in all patients with hematuria. Catheterization itself

**Medical History for Patients with Hematuria**

- Exclude pseudohematuria—drugs, vegetable dyes, pigments
- Factitious—Munchausen syndrome, narcotic-seeking behavior
- Bleeding diathesis
- Clots—indicate nonglomerular bleeding; large, thick clots (bladder); small, stringy clots (upper tract)
- Gross hematuria—relationship to exercise, infection
- Relationship of gross hematuria to urinary stream—initial (urethra distal to the urogenital diaphragm), total (bladder proper or upper urinary tract), terminal (bladder neck or prostatic urethra)
- Painful hematuria—urinary tract infection or calculus, papillary necrosis, passage of clots, obstruction, loin pain—hematuria syndrome, glomerulonephritis
- Genitourinary history—flank trauma or pain frequency; nocturia; dysuria; previous stones, tissue passage, or infections; vaginal or penile discharge; sexual activity; presence of urinary catheter
- Relationship to menstruation—endometriosis
- Sickle cell disease or trait
- Medications
- Systemic symptoms—fever, rash, joint pain, weight loss
- Infectious etiology—night sweats, sore throat, impetigo, recent tooth extraction or other invasive procedure, diarrhea, travel to areas endemic for *Schistosoma haematobium*
- Risk factors for urologic cancer—age older than 40 years, tobacco use, analgesic abuse, pelvic irradiation, cyclophosphamide, *S. haematobium*, occupational exposure to dyestuffs and rubber compounds
- Family history—hematuria, renal disease, sickle cell disease, deafness, bleeding diathesis
- Previous testing—blood pressure, urinalysis, serum chemistries, intravenous pyelogram
- Pregnancies—proteinuria, hypertension (with month of onset)
induces hematuria in approximately 15% of patients, but the amount of bleeding is inconsequential, rarely exceeding 3 RBCs per high-power field. Bedside urine dipstick testing and microscopic analysis of this urine should always be performed. This diagnostic approach will reveal WBCs in addition to RBCs in the presence of infection. Proteinuria and RBC casts are seen with glomerular disease. Patients with these disorders do not require further evaluation in the ED beyond the urinalysis and should be referred to a nephrologist.

By contrast, any patients with gross hematuria or risk factors for significant disease require thorough evaluation before discharge from the ED (Box 97-10). Their renal function should be assessed to rule out the development of renal insufficiency. They also should undergo appropriate imaging tests, although clear consensus is lacking on the appropriate radiographic study. If findings fail to suggest a particular etiologic disorder as a cause for the hematuria, a CT scan with contrast or a renal ultrasound study should be performed. If the possibility of an occult stone is a concern, the CT scan should be ordered without contrast. CT scanning is highly sensitive for stones, masses, and other diseases of the upper urinary tract. It should be avoided in pregnancy and renal insufficiency and with a history of anaphylaxis to contrast medium. In these patients, ultrasound imaging is the modality of choice. It is less sensitive than a CT scan for detecting stones and small masses. Although it is not as sensitive as IVP for identifying lesions of the bladder and ureters, it does provide adequate visualization of the kidney. IVP, angiography, and cystoscopy should be reserved for outpatient evaluations, when diagnostic imaging in the ED with ultrasonography or CT shows no evidence of disease.

**Disposition**

Patients younger than 40 years of age, with no risk factors for severe disease and an ED workup not revealing of a particular cause for their microscopic hematuria, can be discharged with outpatient follow-up to ensure resolution of the hematuria. By contrast, patients with known risk factors or gross hematuria require imaging in the ED. If findings on a subsequent workup are negative, urgent outpatient evaluation is essential, because within 3 to 4 years, a genitourinary malignancy will develop in 1% of older patients with initially negative findings on workup.

The references for this chapter can be found online by accessing the accompanying Expert Consult website.
PERSPECTIVE

Many women present to the emergency department (ED) complaining of either pelvic pain or vaginal bleeding. After the possibility of pregnancy has been eliminated, a primary goal of the ED evaluation is to recognize the presence of a few conditions, such as adnexal torsion, that warrant urgent intervention and others, such as new postmenopausal uterine bleeding, that require reliable outpatient follow-up. Most patients also benefit from relief of symptoms and reassurance.

This chapter specifically addresses the ED management of adnexal torsion, ovarian cysts, abnormal uterine bleeding and the provision of emergency contraception. Vaginal bleeding and pelvic pain in pregnant patients and gynecologic infections are discussed in other chapters.

ADNEXAL TORSION

Principles of Disease

Adnexal torsion accounts for roughly 3% of gynecologic emergencies. Adnexal torsion can occur in young girls and is increasingly recognized as a cause of pelvic pain in postmenopausal women but is still most common in the reproductive years because of the regular development of a corpus luteal cyst during the menstrual cycle. Adnexal torsion is caused by a twisting typically of both the ovary and the fallopian tube on its vascular pedicle. Many cases of torsion (50 to 80%) are associated with an ovarian tumor, typically a benign neoplasm, or with large, heavy cysts, as seen in ovarian hyperstimulation syndrome after in vitro fertilization, or polycystic ovaries. Torsion may be a complication of pregnancy. Torsion of a normal ovary only rarely occurs. A slight predominance of ovarian torsion on the right side has been noted. The reason for this predilection is unclear but may relate to the stabilizing effect of the sigmoid colon on the left side. In adnexal torsion, venous and lymphatic obstruction occurs initially, with subsequent congestion and edema of the ovary, progressing to ischemia and necrosis, and eventual infarction of the ovary. Thrombosis of the ovarian vein and artery can occur as well. The ovary often is salvageable if the diagnosis is made before thrombosis occurs. Because of the dual blood supply of the ovary from both the uterine and ovarian arteries, complete arterial obstruction is rare.

Clinical Features

Adnexal torsion often can be a challenging diagnosis to make, because the classic symptoms of severe, sharp unilateral abdominal pain and nausea may not be present. The presence of known risk factors for adnexal torsion such as an ovarian mass or infertility treatments may suggest the diagnosis. Because the presentation can be variable and often subtle, the diagnosis can be difficult to make. In 87 patients with surgically confirmed torsion, the diagnosis was missed on the first visit in almost one half of the patients. Patients reported pain from several hours to weeks in duration, and almost all had some pain on abdominal palpation. Nausea also was a symptom in many of the patients. Other series report similar findings.

Diagnostic Strategies

Laboratory Tests. No specific laboratory tests are helpful in the evaluation of a patient for suspected adnexal torsion, except for a pregnancy test to exclude ectopic pregnancy. A small percentage of patients may have an elevated white blood cell count above 15,000/µL, but this is not a reliable indicator of adnexal torsion.

Imaging

Ultrasonography. Ultrasound examination is usually the initial imaging test in the evaluation of patients with pelvic pain suggestive of adnexal torsion. Enlargement of the ovary is the most common ultrasound finding. The ovary also may have an abnormal position relative to the uterus. Enlargement of an ovary with a heterogeneous stroma and small, peripherally displaced follicles is the classic ultrasound appearance of torsion but often is not seen (Fig. 98-3). The ultrasound study may reveal a mass in the ovary or evidence of hemorrhage (Fig. 98-4). Free pelvic fluid also may be seen. Hemorrhagic cysts and non-neoplastic masses frequently are associated with torsion. These may have a fluid-filled cystic component, exhibit a complex pattern with debris and septations, or be visualized as a solid mass. The characteristic appearance of torsion may be difficult to appreciate if the ovary is obscured by an associated mass.

Doppler Ultrasound Exam. Doppler ultrasound findings are inconsistent in adnexal torsion. Many cases of surgically proven torsion will have documented blood flow on Doppler exam, because the ovary has a dual blood supply from both the
ovarian and uterine arteries. Also, the torsion may be intermittent, so the findings may vary depending on the time of the exam.\(^7\) If a large mass is present, the examination may be technically difficult to perform.\(^8\) Despite these limitations, the Doppler exam may still be useful. Detection of abnormal venous flow is particularly important in early cases of torsion.\(^9\) (Fig. 98-5). Visualization of the twisting of the pedicle also is possible, and this image of the coiled vessels is referred to as a “whirlpool sign.”\(^10\) Lee and colleagues report an 88% accuracy for torsion when the twisted pedicle or whirlpool sign is visualized.\(^11\)

**Computed Tomography.** When renal colic and appendicitis also are strong considerations in the differential diagnosis for acute pelvic pain, an abdominopelvic CT may be the best initial study, particularly in patients who have a presentation atypical for torsion. In ovarian torsion, CT findings include fallopian tube thickening, smooth wall thickening of the associated adnexal mass, ascites, and uterine deviation to the twisted side.\(^12\) (Fig. 98-6). Associated hemorrhage in patients with hemorrhagic infarction can be seen. A study of surgically confirmed ovarian torsion found that CT correctly diagnosed 5 of 13 cases (38%), as opposed to
ultrasonography, which correctly identified 15 of 21 cases (71%).\textsuperscript{3} As illustrated by this and other studies, negative imaging findings should be interpreted with caution when clinical suspicion is high.

\textit{Magnetic Resonance Imaging}. MRI is not typically ordered in the ED but also may demonstrate findings consistent with torsion. It is particularly helpful in cases in which the diagnosis is not clear, such as those characterized by intermittent pain over days.\textsuperscript{15} Findings on MRI suggestive of torsion are similar to those on CT.\textsuperscript{14} Table 98-1 lists the common imaging findings in ovarian torsion.

\textbf{Laparoscopy}. A diagnostic laparoscopy is the gold standard investigative modality in patients in whom clinical suspicion is high despite negative imaging results. In 100 laparoscopies performed in nonpregnant patients with an acute abdomen, only 29 of the 66 cases of ovarian torsion were diagnosed preoperatively. Laparoscopy also diagnosed other unsuspected conditions including ovarian cysts, appendicitis, and pelvic inflammatory disease.\textsuperscript{16}

\section*{Differential Considerations}

Considerations in the differential diagnosis include other causes of acute lower abdominal pain such as appendicitis, ovarian cyst, urinary tract infection, renal calculi, pelvic inflammatory disease, diverticulitis, and ectopic pregnancy. A pregnancy test and pelvic imaging with either an ultrasound or a CT scan will usually allow distinction between these possibilities.
Management

Once the diagnosis of adnexal torsion is made, the patient should be taken to the operating room as soon as possible. Pediatric patients taken to surgery more than 24 hours later had a zero salvage rate, compared to patients who have the best chance for salvage, who were taken to the operating room within 8 hours. The ovary often will recover even if black in appearance at the time of surgery because of its dual blood supply, so attempts at ovarian salvage are warranted even if the diagnosis is made late. This is particularly true in adolescent patients. Return of ovarian function has been demonstrated in a majority of patients with surgery that saves the ovary. Additional imaging studies, such as MRI, are an option if the diagnosis is not clear. Because torsion of a normal-appearing ovary is very rare, patients with a normal-appearing ovary associated with rupture. Rupture of a corpus luteal cyst frequently is associated with a significant degree of hemorrhage. As with a follicular cyst, rupture may follow a pelvic exam, sexual intercourse, exercise, or trauma. Rupture of a large or complex cyst may result in severe pain and peritoneal signs, particularly if the associated bleeding is considerable. Occasionally, a large cyst may be discovered on a routine pelvic exam as an asymptomatic mass, but this is less common.

Diagnostic Strategies

Laboratory Tests. The initial step in the evaluation of pelvic pain or a pelvic mass is to exclude pregnancy with a urine or serum beta-human chorionic gonadotropin (β-hCG) test. A hematocrit may be valuable in the unstable patient as a marker of blood loss.

Imaging

Ultrasoundography. Ultrasoundography is the standard imaging modality to diagnose and characterize all ovarian pathologic processes and lesions including cysts and masses. Both transabdominal and endovaginal examinations provide useful information. The transabdominal approach permits an overall view of the pelvis and will visualize large masses and pelvic free fluid. Use of the endovaginal probe will provide a detailed picture of the ovary. Figures 98-8 and 98-9 present endovaginal views of a normal ovary, and Figure 98-10 illustrates a simple cyst. Follicular cysts are part of the normal architecture of the ovary, but a cyst is considered to be pathologic if it is larger than 2.5 cm in diameter. Depending on the timing of the scan and the degree of clot formation and lysis, hemorrhage may be seen as well. Ultrasound findings suggestive of malignancy include internal septations, solid elements, internal echoes, daughter cysts, thickened wall, and large amounts of ascitic or free fluid.

Computed Tomography. When considerations in the differential diagnosis of unilateral pelvic pain include renal colic, appendicitis, or other bowel pathology, a CT scan may be the best initial imaging study. CT scan also can demonstrate the

OVARIAN CYSTS AND MASSES

Principles of Disease

Ovarian cysts are the most common gynecologic masses. They may manifest at any stage of life but are seen most frequently in the reproductive years because of the cyclic changes of the ovary associated with menstruation (Fig. 98-7). Most ovarian cysts are benign and resolve with no interventions; less commonly, however, they may either be malignant or associated with significant complications such as hemorrhage or torsion.

The most common type of cyst is a simple, follicular cyst. A follicular cyst develops normally during the first half of the menstrual cycle and is considered pathologic when it is greater than 2.5 cm in diameter. It is thin-walled and typically filled with clear fluid. A corpus luteum is considered to be a corpus luteal cyst when it attains a diameter greater than 3 cm. Several other types of cystic masses can occur in the ovary, including other types of cysts, non-neoplastic lesions such as benign cystic teratoma, and various types of ovarian malignancy.

Clinical Features

The most common presentation for patients with an ovarian cyst is pelvic pain. Rupture of a follicular cyst may produce transient pelvic pain or be associated with dyspareunia or may be asymptomatic. Because of its thin, fragile wall, a follicular cyst may rupture during sexual intercourse or during the pelvic exam.

Follicular cysts are rarely associated with hemorrhage. Presentation of a corpus luteal cyst may vary, ranging from an asymptomatic mass to dull, chronic pelvic pain to severe pain associated with rupture. Rupture of a corpus luteal cyst frequently is associated with a significant degree of hemorrhage. As with a follicular cyst, rupture may follow a pelvic exam, sexual intercourse, exercise, or trauma. Rupture of a large or complex cyst may result in severe pain and peritoneal signs, particularly if the associated bleeding is considerable. Occasionally, a large cyst may be discovered on a routine pelvic exam as an asymptomatic mass, but this is less common.
presence of a cyst and associated complications. A follow-up ultrasound exam may be useful in select cases after the CT scan is obtained, particularly if the cyst is complicated.

**Differential Considerations**

As with adnexal torsion, the differential diagnosis seeks to rule out other causes of pelvic pain such as ectopic pregnancy, pelvic inflammatory disease, urinary tract infections, renal colic, appendicitis, and diverticulitis. Cysts range from the benign to ovarian malignancies, so careful attention to the specific appearance of the cyst is important. Presence of large cysts or masses constitutes a risk factor for adnexal torsion.

**Management**

Patients with a simple cyst and reduction in their symptoms may be safely discharged with referral for outpatient gynecologic follow-up evaluation to ensure resolution of the cyst. Most uncomplicated, simple cysts will resolve within a month. More complex cysts may benefit from gynecology consultation in the ED, particularly if reliable follow-up is unlikely or if the patient is particularly symptomatic.

**ABNORMAL UTERINE BLEEDING IN THE NONPREGNANT PATIENT**

**Principles of Disease**

An understanding of the normal menstrual cycle is valuable in considering potential causes of abnormal uterine bleeding (Fig. 98-11). The menstrual cycle starts on the first day of
menses. During the first part of the menstrual cycle, the endometrium thickens under the influence of estrogen, and a dominant follicle develops in the ovary, releasing an ovum at the midpoint of the cycle. After ovulation, the luteal phase begins and is characterized by production of progesterone from the corpus luteum. Progesterone matures the lining of the uterus, and if implantation does not occur, the corpus luteum dies, accompanied by sharp drops in progesterone and estrogen. These changes typically are followed by menstruation. Menstrual bleeding typically is predictable and cyclic and results from withdrawal of the effects of hormones on the endometrium, which occurs approximately 14 days after ovulation.

Disruption of the hypothalamic-pituitary-ovarian axis from a variety of causes can result in abnormal uterine bleeding. Returning the balance of estrogen and progesterone closer to normal with oral contraceptives will help many patients regulate the cycle, with reduction in or cessation of abnormal uterine bleeding.20-21

Clinical Features

History. Abnormal uterine bleeding is a common presenting problem in the ED. Any of a large number of possible conditions can cause abnormal uterine bleeding, and a systematic history and physical exam can help narrow down the possibilities. Table 98-2 lists some terms frequently used to describe abnormal uterine bleeding.

Vaginal bleeding before the age of menarche is abnormal and is often the result of trauma, such as sexual abuse, or a structural lesion.22 In a woman of reproductive age, abnormal uterine bleeding includes a change in the duration, frequency, or amount of bleeding, or bleeding between menstrual cycles. In the postmenopausal woman, any bleeding 12 months after cessation of cycles is classified as abnormal. The patient should be questioned about the possibility of pregnancy. A pattern of irregular bleeding between cycles or an abrupt change in the previous pattern of bleeding should be determined.24 Systemic disease such as liver disease, diabetes, or thyroid disease may be associated with abnormal uterine bleeding.25 Endometrial cancer is associated with underlying diabetes mellitus, anovulatory cycles, obesity, nulliparity, and age older than 35 years.21 Cervical dysplasia or other genital tract pathology may cause postcoital or irregular bleeding.26 Disruption along the hypothalamus-pituitary-ovarian pathway frequently is the cause of abnormal uterine bleeding. Causes of hypothalamic suppression include excessive exercise, stress, and weight loss.27 Polycystic ovary syndrome (PCOS) results in excess estrogen production.

According to Dilley and colleagues, 10.7% of patients with heavy menstrual bleeding have an underlying coagulation disorder, the most common being von Willebrand’s disease.28 Although most patients with abnormal uterine bleeding do not require evaluation for coagulation disorder, the diagnosis is suggested by a family history of a bleeding disorder, prolonged history of heavy menses, excessive bleeding with surgery or dental procedures, or easy bruising.29 Table 98-3 lists historical factors that can help suggest a potential cause for the bleeding.21 Dysfunctional uterine bleeding is a diagnosis of exclusion in a woman of childbearing age after pregnancy, malignancy, and systemic disease have been ruled out.21 Dysfunctional uterine bleeding typically is classified as anovulatory or ovulatory. Anovulatory bleeding is much more common, resulting from a disturbance of the normal hypothalamic-pituitary-ovarian axis, and is particularly common at the extremes of the reproductive years.20

Physical Exam. With prolonged, heavy bleeding, signs of chronic anemia may be noted on the physical exam. PCOS is a common cause of abnormal uterine bleeding. Physical findings suggestive of PCOS include obesity, acne, hirsutism, and acanthosis nigricans, which is hyperpigmentation typically

seen in the folds of skin in the neck, groin, or axilla. Other causes of bleeding include vaginal or cervical lesions, which may be visible on the speculum exam. A leiomyoma or fibroid uterus may be palpable on the bimanual exam. Patients with endometrial cancer frequently have an enlarged uterus as well.

Differential Considerations

The etiology of abnormal uterine bleeding is extensive and includes systemic disease, structural lesions such as a fibroid uterus, hormonal abnormalities, and iatrogenic causes such as medication side effects. A careful physical exam will exclude vaginal or rectal sources of bleeding.

Management

The likely causative disorder, as well as the amount of bleeding, will guide the ED management. Nonsteroidal anti-inflammatory medications are generally effective for relief of associated cramping pelvic pain. For anovulatory bleeding, combination oral contraceptive pills can help regulate the cycle and also counteract the effects of long-term effects of unopposed estrogen on the endometrium. In a patient who desires contraception and is not heavily bleeding on presentation to the ED, a combination oral contraceptive with 20 to 35 μg of ethinyl estradiol may be prescribed. In the patient with heavy bleeding, an oral contraceptive with 35 μg of estrogen can be taken twice a day for 5 to 7 days until the bleeding stops, at which time the dose is decreased to once a day until the pack is completed. Rarely, a patient will present with uncontrolled bleeding and signs of significant blood loss. These patients should have aggressive resuscitation with saline and blood as with other types of hemorrhagic shock. In these patients, surgical removal of the culprit lesion if one is present, or an urgent dilation and curettage (D&C) procedure may be necessary. Alternatively, intravenous conjugated estrogen (Premarin) may be used. The dose is 25 mg IV every 4 to 6 hours until the bleeding stops.

EMERGENCY CONTRACEPTION

Emergency contraception, agents for which are known as the morning-after pill, consists of therapy to prevent pregnancy after unprotected sexual intercourse. It is estimated that more than 1 million unintended pregnancies could be avoided if emergency contraception were used. The most common reasons cited by patients seeking emergency contraception include failure to use contraception and failure of the contraception method, such as from a broken condom or missed oral
combination pills are effective and should be considered with Plan B, but antiemetics can be offered. The incidence of nausea is much lower if possible but can be given up to 120 hours after intercourse. The Yuzpe method is 87 to 90% effective if the regimen is given within 72 hours; this rate drops to 72 to 87% if the pills are given between 72 and 120 hours.46 Emergency contraception should be administered before 24 hours after inadequately protected intercourse who does not desire pregnancy. A majority of women experience menses within a week of the expected duration of therapy is so brief.43 Emergency contraception has no adverse effects on a developing fetus and does not pose a risk to an established pregnancy. A majority of nonpregnant patients are not aware of the availability of this technology, are not informed about its safety or use, or do not have access to the medications.37,38

Emergency contraception using high-dose estrogen was reported in the early 1960s and began to have widespread use after Yuzpe demonstrated the efficacy of a lower dose combination of estrogen and progestin to prevent pregnancy in 1974,36,39,40 Until recently, the Yuzpe regimen—200 µg of estradiol plus 1.0 mg of levonorgestrel or 2.0 mg of norgestrel taken as two doses 12 hours apart—was the standard for postcoital contraception, but at present, levonorgestrel alone, marketed as Plan B in the United States, is more effective and has largely replaced the Yuzpe method.41 Nausea occurs in 18% of patients using Plan B and in 43% of women taking combination pills.42 Antiemetics given 1 hour before the combination pills are effective and should be considered with use of these pills. The incidence of nausea is much lower with Plan B, but antiemetics can be offered. The package insert of Plan B recommends taking the 0.75 mg pill as soon as possible and the subsequent dose 12 hours later; however, taking the doses simultaneously is equally effective. Emergency contraception should be administered before 24 hours if possible but can be given up to 120 hours after intercourse. The Yuzpe method is 87 to 90% effective if the regimen is given within 72 hours; this rate drops to 72 to 87% if the pills are given between 72 and 120 hours.36

Emergency contraception may be offered to any woman after inadequately protected intercourse who does not desire pregnancy. The typical contraindications to oral contraceptives do not apply to emergency contraception, because the duration of therapy is so brief.43 Emergency contraception has no adverse effects on a developing fetus and does not pose a risk to an established pregnancy. A majority of nonpregnant women experience menses within a week of the expected time, but irregular bleeding may occur.37 It is still possible for a patient who uses emergency contraception to get pregnant in the same menstrual cycle, so she should be advised to use an alternative form of contraception and to obtain a pregnancy test if menses is delayed more than 3 weeks. Advance provision of emergency contraception does not increase the number of unprotected sexual encounters.44-47

In 2007, after FDA approval, Plan B became available nationally over the counter without a prescription. Pregnancy rates as well as sexually transmitted diseases, and sexual activity remained unchanged even though the use of emergency contraception has increased, but the effect on these other outcomes was negligible.48

**DISPOSITION**

A majority of patients with pelvic pain from ovarian cysts or abnormal uterine bleeding without hemodynamic compromise may be managed with specific therapies to minimize symptoms and should be referred to a gynecologist for definitive management on an outpatient basis. Patients with confirmed or suspected adnexal torsion and those with severe, acute abnormal uterine bleeding and hemodynamic instability will require urgent gynecology consultation and hospitalization. Patients who receive emergency contraception could be counseled regarding birth control and have a follow-up pregnancy test should they miss their next period.

**KEY POINTS**

- Adnexal torsion is easily missed on initial presentation. This diagnosis should be a consideration in any patient with known risk factors, even if symptoms are subtle or atypical.
- Abnormal uterine bleeding has a myriad of structural or hormonal causes. A careful history and physical examination and selected imaging can help determine the likely cause.
- Ultrasound examination may distinguish among the various types of ovarian cysts and identify associated complications such as torsion and hemorrhage.
- Emergency contraception is a safe, effective option to prevent undesired pregnancy. Levonorgestrel (progestin) as Plan B is more effective and is associated with fewer side effects than the traditional Yuzpe method.

Background

Stroke is the third leading cause of death in the United States and a leading cause of long-term disability. It affects more than 700,000 patients per year, with an in-hospital mortality rate of 5 to 10% for ischemic stroke and 46% for intracerebral hemorrhage (ICH). Although 50 to 70% of stroke survivors will regain functional independence, 15 to 30% will be permanently disabled, and 20% will require institutional care at 3 months. The estimated cost of stroke for 2007 is $62.7 billion. In terms of emergency care, almost 2% of all 911 calls and 4% of hospital admissions from the emergency department (ED) are for patients with potential strokes.

Stroke can be defined as any vascular injury that reduces cerebral blood flow (CBF) to a specific region of the brain, causing neurologic impairment. The onset of symptoms may be sudden or stuttering, often with transient or permanent loss of neurologic function. Approximately 80% of all strokes are ischemic in origin, caused by the occlusion of a cerebral vessel. The rest are hemorrhagic strokes due to the rupture of a blood vessel into the parenchyma of the brain (ICH) or into the subarachnoid space (subarachnoid hemorrhage [SAH]). Only ischemic stroke and ICH are discussed in this chapter.

In the past, treatment for stroke consisted of stabilization, observation, and rehabilitation. In recent years, a better understanding of the pathophysiology of neuronal injury and the introduction of new therapies have led to a shift to early evaluation and treatment. Current interventional treatment regimens include blood pressure management, anticoagulation, thrombolytic therapy, catheter-based interventions, and surgery. The key to success is early identification and treatment of patients with stroke before neurologic deficits become irreversible.

Epidemiology

Ischemic Stroke

An estimated 430,000 “first-ever” ischemic strokes occur each year in the United States, of which 10 to 15% are transient ischemic attacks (TIAs). These may result either from in situ thrombosis or embolic obstruction from a more proximal source, usually the heart. In more than one third of these first-ever strokes, no cause is found (Table 99-1).

Approximately one third of all ischemic strokes are thrombotic in nature. These can be due to either large- or small-vessel occlusions. The incidence of large-vessel occlusions is higher among men than among women and among whites than black Americans. Common areas for large-vessel occlusions are cerebral vessel branch points, especially in the distribution of the internal carotid artery. Thrombosis usually results from clot formation in the area of an ulcerated atherosclerotic plaque (which forms in the area of turbulent blood flow, such as a vessel bifurcation). A marked reduction in flow results when the stenosis occludes more than 90% of the blood vessel diameter. With further ulceration and thrombosis, platelets adhere to the region. A clot then either embolizes or occludes the artery.

Lacunae, or small-vessel strokes, involve small terminal sections of the vasculature and more commonly occur in black Americans and patients with diabetes and hypertension. A history of hypertension is present in 80 to 90% of patients who experience lacunar strokes. The subcortical areas of the cerebrum and brainstem are often involved. The infarcts range in size from a few millimeters to 2 cm and are seen most commonly in the basal ganglia, thalamus, pons, and internal capsule. They may be caused by small emboli or by a process termed lipohyalinosis, which occurs in patients with hypertensive cerebral vasculopathy. Although nearly 20 lacunar syndromes have been described, the most common of these lacunar syndromes are pure motor strokes, pure sensory strokes, or atracile hemiparesis. Because they are subcortical and well localized, lacunar strokes do not cause cognitive impairment, aphasia, or simultaneous sensorimotor findings.

One fourth of all ischemic strokes are cardioembolic in nature. Embolization of a mural thrombus in patients with atrial fibrillation is the most common pathomechanism, and patients with atrial fibrillation have a four- to fivefold increased risk for development of a stroke. Almost 20% of stroke patients will have atrial fibrillation on their admission electrocardiogram (ECG). Strokes due to atrial fibrillation are more likely to involve large cerebral vessels, to be more severe, and to carry a higher mortality rate. Noncardiac sources of emboli may include diseased portions of extracranial arteries, resulting in an artery-to-artery embolus. One common example is amaurosis fugax, in which emboli from a proximal carotid artery plaque embolizes to the ophthalmic artery, causing transient monocular blindness.

Approximately 12.2 ischemic strokes per 1000 nonfatal myocardial infarctions (MIs) occur within 1 month after the index event. Furthermore, 11.1 ischemic strokes per 1000 nonfatal MIs occur during the patient’s hospitalization. Independent predictors of stroke after acute MI are advanced age, diabetes,

TIA, transient ischemic attack.

Hypertension, history of previous stroke, anterior location of index MI, previous MI, atrial fibrillation, heart failure, and nonwhite race. The use of aspirin has been shown to reduce the incidence of post-MI stroke by 46%.12

Approximately 3 to 4% of all strokes occur in patients between the ages of 15 and 45 years. Although atherosclerosis is the most common cause in older patients, causative disorders and conditions in younger patients often are uncommon or are reversible. Pregnancy, the use of oral contraceptives, antiphospholipid antibodies (such as lupus anticoagulant and anticardiolipin antibodies), protein S and C deficiencies, and polycythemia all predispose patients to sludging or thrombosis, thereby increasing the risk of stroke. Fibromuscular dysplasia of the cerebral vasculature also may lead to stroke, and in rare instances, prolonged vasoconstriction from a migraine syndrome causes stroke. Recreational drugs such as cocaine, phenylpropanolamine, and amphetamines are potentiators of vasoconstriction that have been associated with both ischemic and hemorrhagic stroke.

Carotid and vertebral dissections often are associated with trauma but may follow such mild events as turning the head sharply. Carotid and vertebral dissections also are seen more frequently in people with underlying pathology of the vessel wall, such as in fibromuscular dysplasia and connective tissue disorders. Alteration in the vessel intima can lead to vessel stenosis, occlusion, or embolism. The patient may report a minor preceding event such as spinal manipulation, yoga, working overhead, coughing, or vomiting.13 Presenting manifestations may include headache, facial pain, visual changes, cranial nerve palsies, pain over the affected vessel, Horner’s syndrome, amaurosis fugax, subarachnoid hemorrhage, or an ischemic stroke. The headache frequency is unilateral and may occur days before onset of the other neurologic symptoms.13 Although angiography has been the standard diagnostic study, dissections are increasingly being diagnosed by less invasive modalities such as ultrasonography, magnetic resonance imaging (MRI), and computed tomography angiography (CTA).14 Medical therapy includes early anticoagulation if SAH is not suspected. If symptoms recur despite anticoagulation, the patient may be eligible for endovascular intervention. Carotid or vertebral dissection is not considered a contraindication to use of tissue plasminogen activator (t-PA) in the eligible patient.13 This entity is considered a major cause of stroke in younger patients.13,15,16,17

A TIA was historically defined as a neurologic deficit that has complete clinical resolution within 24 hours. A newer definition of TIA proposed by Albers18 is a “brief episode of neu-
is more common in younger patients than hypertensive ICH. Such patients may have no history of hypertension.

**PRINCIPLES OF DISEASE**

**Pathophysiology**

The cerebral vasculature supplies the brain with a rich flow of blood that contains the critical supply of oxygen and glucose necessary for normal brain function. When a stroke occurs, there are immediate alterations in CBF and extensive changes in cellular homeostasis. A complete interruption of CBF, which is rare, results in loss of consciousness within approximately 10 seconds and death of vulnerable pyramidal cells of the hippocampus within minutes. In stroke, collateral circulation helps maintain some blood flow to the ischemic region. The normal CBF is 40 to 60 mL/100 g of brain per minute. When CBF drops below 15 to 18 mL/100 g of brain per minute, several physiologic changes occur. The brain loses electrical activity, becoming electrically “silent,” although neuronal membrane integrity and function remain intact. Clinically, the areas of the brain maintaining electrical silence manifest a neurologic deficit, even though the brain cells are viable. When CBF is below 10 mL/100 g of brain per minute, membrane failure occurs, with a subsequent increase in the extracellular potassium and intracellular calcium and eventual cell death. The ischemic penumbra is the area of the brain surrounding the primary injury, which is preserved by a tenuous supply of blood from collateral vessels. This border zone of neuronal tissue is the area of greatest interest to investigators for possible salvage in both ischemic and hemorrhagic stroke. As defined by CBF, the ischemic penumbra consists of brain tissue with blood flow of 10 to 18 mL/100 g of brain per minute in which electrical silence is present but irreversible damage has not yet occurred. In ischemic stroke, the duration of occlusion plays a critical role in neuronal survival. Increasing the duration of occlusion increases both the irreversibility of deficits and the amount of cerebral infarction. In experimental animals, occlusion of cerebral vessels for longer than 6 hours leads to irreversible neurologic deficits. Thus, ischemic stroke trials using fibrinolytic or antiplatelet agents have attempted to recanalize occluded arteries and reperfuse ischemic areas of the brain within a 2- to 6-hour therapeutic window. In patients with ICH, a complicated series of events including red blood cell lysis and increased blood-brain barrier permeability can lead to edema formation and secondary brain injury. Using a protocol similar to that in ischemic stroke trials, investigators have begun looking at the feasibility of ultra-early hematoma evacuation in patients with ICH. Cerebral artery feeds the lenticulostriate branches that supply the putamen, part of the anterior limb of the internal capsule, the lentiform nucleus, and the external capsule. Main cortical branches of the middle cerebral artery supply the lateral surfaces of the cerebral cortex from the anterior portion of the frontal lobe to the posterolateral occipital lobe.

Although the posterior circulation is smaller and supplies only 20% of the brain, it supplies the brainstem (which is critical for normal consciousness, movement, and sensation), cerebellum, thalamus, auditory and vestibular centers of the ear, medial temporal lobe, and the visual occipital cortex. The posterior circulation is derived from the two vertebral arteries that ascend through the transverse processes of the cervical vertebrae. The vertebral arteries enter the cranium through the foramen magnum and supply the cerebellum by the posterior inferior cerebellar arteries. They join to form the basilar artery, which branches to form the posterior cerebral arteries. The extent of injury in either an anterior or a posterior stroke depends on both the vessel involved and the presence of collateral blood flow distal to the vessel occlusion. A patient with excellent collateral blood flow from the contralateral hemisphere may have minimal clinical deficits despite a complete carotid occlusion. By contrast, a patient with poor collateral flow may have hemiplegia with the same lesion.

**Anatomy and Physiology**

Blood is supplied to the brain by the anterior and posterior circulations. The anterior circulation originates from the carotid system and perfuses 80% of the brain including the optic nerve, retina, and frontoparietal and anterior-temporal lobes. The first branch off the internal carotid artery is the ophthalmic artery, which supplies the optic nerve and retina. As a result, the sudden onset of painless monocular blindness (amaurosis fugax) identifies the stroke as involving the anterior circulation (specifically the ipsilateral carotid artery) at or below the level of the ophthalmic artery. The internal carotid arteries terminate by branching into the anterior and middle cerebral arteries at the circle of Willis.

The anterior cerebral artery supplies the basal and medial aspects of the cerebral hemispheres and extends to the anterior two thirds of the parietal lobe (Fig. 99-1). The middle cerebral artery feeds the lenticulostriate branches that supply the putamen, part of the anterior limb of the internal capsule, the lentiform nucleus, and the external capsule. Main cortical branches of the middle cerebral artery supply the lateral surfaces of the cerebral cortex from the anterior portion of the frontal lobe to the posterolateral occipital lobe.

**CLINICAL FEATURES**

**Ischemic Stroke**

The signs and symptoms of an ischemic stroke may appear suddenly and without warning or may have a stuttering, insidious onset. Disruption of the flow to one of the major vascular limbs of the cerebral circulation will result in physiologic disruption to the anatomic area of the brain supplied by that blood vessel. Ischemic strokes can be classified as anterior or posterior circulation strokes depending on the vasculature involved. The presence of neurologic deficits is highly dependent on collateral flow. In addition to the vascular supply involved, ischemic strokes can be further described by the
A “stroke in evolution” is one in which focal neurologic deficits worsen over the course of minutes or hours. Approximately 20% of anterior circulation strokes and 40% of posterior circulation strokes will show evidence of progression. Anterior circulation strokes may progress within the first 24 hours, whereas posterior strokes may progress for up to 3 days. Propagation of thrombus is postulated as a likely mechanism for progression.

With anterior circulation strokes (involving variously and primarily the carotid, anterior, and middle cerebral arteries), the clinical presentation rarely includes complete loss of consciousness unless the lesion occurs in the previously unaffected hemisphere of a patient who has experienced a previous contralateral stroke. Oclusions in the anterior cerebral artery mainly affect frontal lobe function. The patient has altered mentation coupled with impaired judgment and insight, as well as the presence of primitive grasp and suck reflexes on physical exam. Bowel and bladder incontinence may be features. Paralysis and hyposthesia of the lower limb opposite the side of the lesion are characteristic. Leg weakness is more pronounced than arm weakness in anterior cerebral distribution stroke. Apraxia or clumsiness in the patient’s gait also may be noted.

Marked motor and sensory disturbances are the hallmarks of occlusion of the middle cerebral artery. They occur on the side of the body contralateral to the side of the lesion and usually are worse in the arm and face than the leg. Such disturbances may involve only part of an extremity or the face but will almost always be accompanied by numbness in the same region as that of the motor loss. Hemianopsia, or blindness in one half of the visual field, occurs ipsilaterally to the lesion. Agnosia, or the inability to recognize previously known subjects, is common, and aphasia may be present if the lesion occurs in the dominant hemisphere. Patients often have a gaze preference toward the affected hemisphere because of disruption of the cortical lateral gaze centers. The clinical aphorism is that a patient looks at a destructive lesion (stroke) but away from an irritative lesion (seizure focus).

Aphasia, a disorder of language in which the patient articulates clearly but uses language inappropriately or understands it poorly, also is common in dominant-hemisphere stroke. Aphasia may be expressive, receptive, or a combination of both. Wernicke’s aphasia occurs when the patient is unable to process sensory input such as speech and thus fails to understand verbal communication (receptive aphasia). Broca’s aphasia refers to the inability to communicate verbally in an effective way, even though understanding may be intact (expressive aphasia). Aphasia should be distinguished from dysarthria, which is a motor deficit of the mouth and speech muscles; the dysarthric patient articulates poorly but understands words and word choices. Aphasia is important to recognize because it usually localizes a lesion to the dominant (usually left) cerebral cortex in the middle cerebral artery distribution. Aphasias and dysphasias are terms that are used interchangeably but must be distinguished from dysphasia, which is difficulty in swallowing.

Pathology in the vertebrobasilar system (i.e., posterior circulation strokes) can cause the widest variety of symptoms and as a result may be the most difficult to diagnose. The symptoms reflect cranial nerve deficits, cerebellar involvement, and involvement of neurosensory tracts. The brainstem also contains the reticular activating system, which is responsible for mediating consciousness, and the emesis centers. Unlike those with anterior circulation strokes, patients with posterior circulation stroke can present with loss of consciousness and frequently have nausea and vomiting. The posterior cerebral artery supplies portions of the parietal and occipital lobes, so vision and thought processing are impaired. Visual agnosia, the inability to recognize seen objects, may be a feature, as may alexia, the inability to understand the written word. A third nerve palsy may occur, and the patient may experience homonymous hemianopsia. One of the more curious facets of this syndrome is that the patient may be unaware of any visual problem (visual neglect). Vertigo, diplopia, visual field defects, weakness, paralyses, dysarthria, dysphagia, syncope, spasticity, ataxia, or nystagmus may be associated with vertebrobasilar artery insufficiency. Posterior circulation strokes also demonstrate crossed deficits, such as motor deficits on one side of the body and sensory loss on the other. In anterior circulation strokes, by contrast, abnormalities are always limited to one side of the body.

A focused neurologic exam should assess level of consciousness, speech, cranial nerve function, motor and sensory function, and cerebellar function. Level of consciousness and fluency of speech can be rapidly assessed in a dialogue with the patient to determine the presence of dysarthria or aphasia. The head should be evaluated for signs of trauma. Pupillary size and reactivity and extraocular movements provide important information about brainstem function, particularly cranial nerves (CN) III through VI; an abnormal third nerve function may be the first sign of tentorial herniation. Gaze preference suggests brainstem or cortical involvement. Central facial nerve weakness from a stroke should be distinguished from the peripheral causes of CN VII weakness. With a peripheral lesion, the patient is unable to wrinkle the forehead. Assessment of facial sensation, eyebrow elevation and squinting, smiling symmetry, gross auditory acuity, gag reflex, shoulder elevation, sternocleidomastoid strength, and tongue protrusion complete the cranial nerve examination.

Motor and sensory testing is performed next. Muscle tone can be assessed by moving a relaxed limb. Proximal and distal muscle group strength should be assessed against resistance. Pronator drift of the arm is a sensitive sign of motor weakness and can be tested simultaneously by having the patient sit with eyes closed and arms outstretched, with palms toward the ceiling, for 10 seconds. Asymmetrical sensation to pain and light touch may be subtle and difficult to detect. Double simultaneous extinction evaluation tests for sensory neglect and can be easily performed by simultaneously touching the right and left limbs. The patient may feel both the right and left sides being touched individually but may not discern touch on one side when both are touched simultaneously. Similarly, the ability to discriminate a number gently scratched on a forearm, graphesthesia, is another easily tested cortical parietal lobe function. These tests can help differentiate a pure motor deficit of a lacunar stroke from a sensorimotor middle cerebral artery deficit.

Cerebellar testing and the assessment of reflexes and gait complete the examination. Finger-to-nose and heel-to-shin evaluations are important tests of cerebellar functions. Asymmetry of the deep tendon reflexes or a unilateral Babinski’s sign may be an early finding of corticospinal tract dysfunction. Gait testing is commonly omitted yet is one of the most informative parts of the neurologic examination. Observing routine ambulation and heel-to-toe walking can assess for subtle ataxia, weakness, or focal cerebellar lesions.

The National Institutes of Health Stroke Scale (NIHSS) is a useful and rapid tool for quantifying neurologic deficit in patients with stroke and can be used in determining treatment options (Box 99-2). NIHSS scores have been shown to be reproducible and valid and to correlate well with the amount of infarcted tissue on CT scan. The baseline NIHSS can identify patients who are appropriate candidates for fibrinolytic therapy as well as those at increased risk for hemorrhage.

Hemorrhagic Stroke

The classic presentation of ICH is the sudden onset of headache, vomiting, severely elevated blood pressure, and focal neurologic deficits that progress over minutes. Similar to ischemic stroke, ICH often is associated with a motor and sensory deficit contralateral to the brain lesion. The patient may present with agitation and lethargy but may quickly deteriorate, with progression to stupor or coma. Almost 40% will demonstrate significant growth in hemorrhage volume within the first few hours.41 Although headache, vomiting, and coma are common, a significant proportion of patients do not have these findings, and the clinical presentation may be similar to that of patients with ischemic stroke (Table 99-2).

Ongoing assessment of airway and mental status is of paramount importance in patients with ICH because precipitous deterioration is always a possibility. The respiratory pattern also may be affected in hemorrhagic stroke. Cheyne-Stokes respirations (increasing and decreasing depth of respirations with periods of apnea) may occur with a large ICH. Putaminal hemorrhages may cause deep, irregular respirations, whereas patients with cerebellar hemorrhage may have a normal respiratory pattern.

The pupillary examination can be extremely helpful in determining the location and extent of the insult. Pontine hemorrhage classically manifests with pinpoint pupils because of the interruption of the descending sympathetic tracts and unopposed parasympathetic stimulation. Dilated pupils may result from bleeding into the putamen, whereas bleeding into the thalamus may manifest with anisocoria, miosis, or a sluggish pupillary response. Cranial nerve abnormalities may result from cerebellar hemorrhages. The parasympathetic fibers course along the outside of CN III. As a result, compression of the nerve results in loss of pupillary reactivity before anisocoria. As noted previously, the physical exam may be insufficient to distinguish an ischemic stroke from an ICH, and radiographic confirmation is required.

As with ischemic stroke, a careful neurologic exam is important in localizing the region and extent of injury. Baseline NIHSS and Glasgow Coma Scale (GCS) scores can be used to assess stroke severity, although the GCS score may be more feasible to follow for neurologic deterioration (Box 99-3).

Poor prognostic indicators for patients with ICH include a decreased level of consciousness on arrival, intraventricular hemorrhage, and an ICH volume of greater than 40 cc, all of which can be assessed in the ED. The ABC/2 technique is a quick and accurate method of measuring ICH volume at the bedside22 (see Fig. 99-1).

### Differential Considerations

**Ischemic Stroke**

Extra-axial collections of blood secondary to trauma can mimic stroke. An epidural or subdural hematoma can cause an altered mental status, focal neurologic signs, and rapid progression to coma. Elderly patients, who represent the age group at highest risk for stroke, can be victims of recurrent falls that lead to chronic subdural hematomas. Carotid dissection may occur after neck trauma or sudden hyperextension and may be associated with focal neurologic signs and symptoms, as with an aortic dissection that extends into the carotid arteries. The diagnosis is supported by a compatible history or relevant findings on contrast angiography or magnetic resonance angiography (MRA).

Other structural lesions that may cause focal neurologic signs include brain tumors and abscesses. Air embolism should be suspected in the setting of marked atmospheric pressure changes, such as in scuba diving or during medical procedures or injuries that may allow air into the vascular system. Seizures, altered mental status, and focal neurologic findings also may be manifestations of air embolism.

Metabolic abnormalities also can mimic stroke syndromes. Hypoglycemia often is responsible for an altered mental status and is a well-known cause of sustained focal neurologic symptoms that can persist for several days. Wernicke’s encephalopathy causes ophthalmoplegia, ataxia, and confusion that can be mistaken for signs of cerebellar infarction.

Migraine may present with focal neurologic findings, with or without headache. A seizure followed by Todd’s postictal paralysis may mimic stroke. Bell’s palsy, labyrinthitis, peripheral nerve palsy, and demyelinating diseases may also mimic stroke. Meniere’s disease may be difficult to distinguish from a posterior circulation stroke or TIA. Dizziness, vertigo, hearing loss, and tinnitus in Meniere’s disease are common, whereas difficulties with vision, speech, or other focal symptoms are uncommon.

Like stroke, giant cell arteritis is a disease of the elderly. It may cause severe headache, visual disturbances, and, rarely, aphasia and hemiparesis. Other symptoms include intermittent fever, malaise, jaw claudication, morning stiffness, and
myalgias. The diagnosis should be suspected in patients with a very high erythrocyte sedimentation rate (ESR) and is confirmed by temporal artery biopsy. Collagen vascular diseases such as polyarteritis nodosa, lupus, and other types of vasculitis may cause stroke syndromes.

Venous sinus thrombosis is another cause of focal neurologic symptoms that most commonly affects the superior sagittal sinus and lateral sinuses. The cerebral venous sinuses receive blood from the cortical veins and deep veins. A venous sinus can become occluded through thrombus formation or compression (such as from a tumor or abscess). If collateral circulation is not sufficient, cerebrospinal fluid pressures can become elevated and venous congestion can develop, resulting in petechial or hemorrhagic infarction. Multiple risk factors predisposing affected patients to venous sinus thrombosis are recognized, including trauma, infectious processes, hypercoagulable states, low-flow states, compression of the venous sinus, dehydration, various drugs (such as androgens, “ecstasy,” and oral contraceptives), and pregnancy or the postpartum state. In many patients, no predisposing risk factor will be identified until further workup is completed.

The diagnosis of cerebral venous thrombosis can be difficult because of the nonspecific nature of symptoms, as well as the variable time frame of symptom onset (from hours to a few weeks). Patients may present with generalized headaches, nausea, vomiting, paresis, visual disturbances, depressed level of consciousness, seizures or even symptoms generally ascribed to psychiatric disorders (such as depression). Depending on the location of the thrombus, physical examination of the patient may reveal papilledema, proptosis, or palsies of cranial nerves III, IV, and VI, as well as other focal neurologic signs and symptoms.

The diagnosis of cerebral venous thrombosis sometimes can be made by CT. The so-called delta sign can be seen on a noncontrast CT scan as a dense triangle in the superior sagittal sinus. On a contrast-enhanced CT scan, this same area will lack demonstration of full contrast (the empty delta sign) owing to presence of thrombus in portions of the vessel's lumen. At many institutions, MRI and magnetic resonance venography (MRV) are the preferred modalities for the noninvasive detection of cerebral venous thrombosis. These studies can diagnose cerebral venous thrombosis by visualizing thrombus within a vessel and provide evidence of hemorrhagic foci or of dilated venous collateral circulation.

The treatment of venous sinus thrombosis includes the use of heparin even in those patients with demonstrated hemorrhage. There is no evidence that low-molecular-weight heparin is superior to unfractionated heparin. In some cases, thrombotic agents have been directly infused into the thrombus using endovascular techniques. Neurosurgical intervention has not been proved to be of benefit. The mortality rate from venous sinus thrombosis is approximately 10%. In view of the nonspecific nature of the symptoms, it is important to keep this diagnosis in mind. In women who are pregnant or have recently given birth, the possibility of venous sinus thrombosis should be a primary consideration in the setting of new-onset neurologic disorders.

Hemorrhagic Stroke

The differential diagnosis for ICH is similar to that for ischemic stroke; considerations include migraine, seizure, tumor, abscess, hypertensive encephalopathy, and trauma. Hypertensive encephalopathy and migraine also can manifest with headache, nausea, and vomiting. Although focal neurologic signs are uncommon, they may occur with these entities. With hypertensive encephalopathy, patients usually exhibit marked elevation in blood pressure and other evidence of end-organ injury, including proteinuria, cardiomegaly, papilledema, and malignant hypertensive retinopathy. These patients usually improve significantly with treatment of their hypertension. Migraines frequently are associated with an aura, and the patient often has a history of similar headaches. The differentiation between ICH and labyrinthitis can be especially difficult in the elderly. The abrupt onset of vertigo, vomiting, and nystagmus can represent a peripheral process such as labyrinthitis or a central process such as cerebellar or brainstem infarct or hemorrhage. Age older than 40 years and a history of hypertension or other risk factors for ICH increase the possibility of a cerebellar hemorrhage. Pathologic features specifically referable to the brainstem must be sought. These include hiccups, diplopia, facial numbness, dysphagia, and ataxia. Vertebral patients often have a strong desire to remain immobile with the eyes closed, but this must not preclude a thorough cranial nerve and cerebellar examination, including gag. Gross ataxia should be present with cerebellar stroke and absent with labyrinthine disease. A head CT scan should be strongly considered in patients older than 40, to assist in differentiating between labyrinthitis and cerebellar hemorrhage.

■ DIAGNOSTIC STRATEGIES

Ischemic Stroke

Although clinical data can help establish the diagnosis, cause, and location of the stroke, confirmatory diagnostic tests often are required to establish the final etiology or to eliminate other causes for the deficits. The immediate ED evaluation should include a blood glucose determination, cranial imaging (CT or MRI scan), and an ECG.

An emergent noncontrast cranial CT is the standard initial imaging technique for evaluating a patient with a potential stroke in the ED. It can quickly differentiate an ischemic stroke from ICH and other mass lesions. This information is crucial to subsequent therapeutic decisions. A CT scan can identify almost all parenchymal bleeds larger than 1 cm in diameter. Recent studies have yielded a sensitivity of 92 to 98% for the detection of SAH by CT scan; however, recent small studies suggest that sensitivity may be even higher with fifth-generation CT scanners. More research is needed to confirm the sensitivity of these fifth-generation CT scanners, owing to small sample sizes in studies examining this issue to date. In a majority of ischemic strokes, gross signs of infarction will not appear on routine CT scans for at least 6 to 12 hours, depending on the size of the infarct. However, subtle, early ischemic changes have been noted in up to 60 to 80% of noncontrast CT scans within the first 3 hours in patients with middle cerebral artery occlusions. These early ischemic changes include the hyperdense artery sign (acute thrombus in a vessel), sulcal effacement, loss of the insular ribbon, loss of gray-white interface, mass effect, and acute hypodensity (Fig. 99-2). Additionally, CTA can be used to identify the presence of intravascular thrombosis, vasculature dissection, or stenosis. In cases in which arterial dissection is suspected, imaging with MRA or CTA is indicated.

The clinical importance of early ischemic CT findings in regard to fibrinolytic therapy within 3 hours of symptom onset is questionable because the ability of treating physicians to reproducibly identify these findings is poor and their clinical significance is questionable. Only acute hypodensity and mass effect have been shown to be associated with an increased risk of ICH after fibrinolysis (over that in treated patients without these findings). However, these findings do not
exclude appropriate patients from fibrinolytic therapy, because the chance for excellent neurologic outcome at 3 months was better with such therapy than with placebo despite the presence of such abnormalities, and the risk of symptomatic ICH, severe disability, or death at 3 months was no different between treatment groups. Patients with a hyperdense artery sign and acute hypodensity of one third of the middle cerebral artery occlusion of both large and small blood vessels of the head allows a noninvasive method of demonstrating large-vessel occlusions of the anterior and posterior circulation, though small intracranial vascular occlusions may not be readily apparent. With the improvements in MRI and MRA speed and resolution, some stroke centers are replacing CT protocols with limited “stroke protocol” MRI or MRA as the initial imaging modality of choice. The choice of initial cranial imaging modality is highly dependent on the speed with which these scans can be done and interpreted at each individual center.

Diffusion-weighted imaging (DWI) and perfusion-weighted imaging (PWI) are MRI techniques that take minutes to perform and may allow differentiation between reversible and irreversible neuronal injury. In one study of patients with DWI-PWI mismatch, 30-day clinical outcomes were better after early reperfusion than without such early reperfusion (56% and 19%, respectively). Of importance, however, early reperfusion in patients without DWI-PWI mismatch did not result in a favorable outcome. Currently, further studies are being performed by clinicians and researchers to determine if t-PA administration in patients with DWI-PWI mismatch can increase reperfusion rates and limit expansion of the DWI lesion.

Other potential imaging modalities include CTA and perfusion scans. In CTA, a computed tomography (CT) scan is enhanced by an intravenous contrast agent to better define the vasculature of the brain. Areas of vascular stenosis and occlusion can be visualized with this technique. This information can then be used by interventionalists to determine whether or not a lesion is amenable to intra-arterial t-PA therapy or mechanical retrieval. Also requiring intravenous contrast, perfusion CT scans can reveal perfusion deficits within different regions of the brain. Additionally, CTA and perfusion CT can differentiate reversible from irreversible ischemic insults.

Further studies using these newer imaging techniques to determine eligibility for thrombolytic therapy are ongoing. An ECG should be obtained because atrial fibrillation and acute MI are associated with up to 60% of all cardioembolic strokes. The hematology evaluation should include a complete blood count with platelet count and coagulation studies. A toxicologic screen and cardiac isoenzyme assay should be considered if appropriate. Elevated blood viscosity even when hematocrit levels are not frankly polycythemic can affect blood flow and prognosis. A platelet count can identify thrombocytosis or thrombocytopenia, which may precipitate a thrombosis or hemorrhage. Coagulation studies are especially helpful to guide management for patients in whom anticoagulation is being considered or for patients with a hemorrhagic stroke. Cocaine or amphetamine ingestion should be considered with either an ischemic or hemorrhagic stroke in patients younger than 40 years of age.

Other ancillary diagnostic tests to consider include an echocardiogram, carotid duplex scan, and angiogram. Some centers are performing these studies as part of an observation unit protocol in the ED. An echocardiogram can identify a mural thrombus, tumor, patent foramen ovale, or valvular vegetation in those patients in whom a cardioembolic stroke is suspected. An echocardiogram also should be considered in patients with no obvious cause for their stroke. Carotid duplex scanning may be helpful in patients with known or suspected high-grade carotid stenosis with worsening neurologic deficit or crescendo TIAs. These patients may be candidates for heparinization or emergent carotid endarterectomy. Carotid duplex studies can accurately identify carotid artery stenosis with occlusion of more than 60% vessel diameter, but an angiogram is required to distinguish 95% stenosis from a complete occlusion.

Angiography is the definitive test to demonstrate stenosis or occlusion of both large and small blood vessels of the head.

Figure 99-2. A, CT scan taken 2 hours and 50 minutes after a large right middle cerebral artery occlusion. There are subtle, ultra-early ischemic changes, including loss of the gray-white interface (arrows) and subtle evidence of sulcal effacement. B, CT scan of same patient approximately 8 hours after symptom onset shows acute hypodensity (arrows) and more prominent sulcal effacement.

The role of MRI in the ED evaluation of stroke continues to evolve. MRI can visualize ischemic infarcts earlier and identify acute posterior circulation strokes more accurately than CT. In addition, recent studies suggest that it is as effective as CT in identifying ICH. However, availability, difficulty in accessing critically ill patients, and scan time limit its general use. Advances in MRA technology have allowed a noninvasive method of demonstrating large-vessel occlusions of the anterior and posterior circulation, though small intracranial vascular occlusions may not be readily apparent. With the improvements in MRI and MRA speed and resolution, some stroke centers are replacing CT protocols with limited “stroke protocol” MRI or MRA as the initial imaging modality of choice. The choice of initial cranial imaging modality is highly dependent on the speed with which these scans can be done and interpreted at each individual center.
and neck. It can detect subtle abnormalities, such as with dissection, that may not be demonstrated with other imaging techniques.

**Hemorrhagic Stroke**

The hematologic evaluation for the patient with hemorrhagic stroke should be performed in the same manner as for the patient with ischemic stroke. Particular attention should be directed to uncovering the presence of a coagulopathy. A drug screen should be obtained to evaluate for use of sympathomimetics if substance abuse is suspected. Increased sympathetic outflow secondary to the hemorrhage may lead to an increase in dysrhythmias. Dysrhythmias also may signal impending brainstem compression from an expanding hemorrhage.

As in ischemic stroke, the cranial CT scan is the diagnostic test of choice to evaluate for an ICH. The CT scan will reliably diagnose up to 95% of ICHs, although very small lesions may not be visible. Hemorrhages that are several days old may appear as isodense regions.

### STROKE MANAGEMENT

**Ischemic Stroke**

With the recent focus on rapid recognition, evaluation, and treatment of stroke, EDs have attempted to streamline the care of these patients to meet recommended time goals (Table 99-3). This has led to the development of various stroke protocols, critical pathways, and acute interventional stroke teams that often are deployed in the field before the patient even arrives to the ED.

In the prehospital setting, the focus should be on maintenance of the “ABCs” (airway-breathing-circulation), rapid identification, early hospital notification, and rapid transport. Although it is unusual for patients with ischemic stroke to be unresponsive on presentation, their ability to communicate may be altered secondary to dysphasia. After an ischemic stroke, patients usually can maintain their airway unless the brainstem is affected or unless significant cerebral edema is compressing the opposite hemisphere. Patients with intact protective airway reflexes should receive oxygen if they are hypoxic (oxygen saturation less than 95%), and a monitor and intravenous line established.

Overhydration should be avoided to prevent cerebral edema. By contrast, dehydration may lead to decreased cerebral perfusion, and saline infusion should be given if dehydration is suspected. Dextrose-containing solutions should be avoided in normoglycemic patients suspected of having had a stroke, because elevated blood glucose levels may worsen an ischemic deficit. Out-of-hospital personnel should attempt to rapidly ascertain the patient’s blood sugar. If this is not possible, glucose should be given only to diabetic patients in whom hypoglycemia is strongly suspected. Electrocardiographic monitoring is necessary because of the frequency of cardiac causes of ischemic stroke.

The circumstances surrounding the stroke as well as concomitant medical conditions should be ascertained. The initial out-of-hospital responders should document the exact time the patient was last seen to be neurologically normal and the level of neurologic functioning; reversible defects may completely resolve by the time the patient has arrived at the hospital. The level of consciousness, gross focal motor deficits, difficulty with speech, clumsiness, facial asymmetry, and any other focal deficits should be noted. Prehospital stroke scales have been developed to assist in differentiating patients who have had a stroke from those who have not and to identify potential candidates for fibrinolytic therapy. Early recognition, notification, and transport by emergency medical service (EMS) and other out-of-hospital personnel have been shown to be valuable in enabling early treatment.

In the ED setting, the ABCs should be reassessed on an ongoing basis, because patients may experience rapid deterioration, even with subacute stroke. They may be found at home 1 or 2 days after the event has occurred and may have concomitant illnesses, such as aspiration pneumonia, dehydration, hypothermia, rhabdomyolysis, or myocardial ischemia. Fever necessitates a thorough evaluation to identify the source of infection, followed by prompt institution of appropriate treatment. As supported by strong evidence, even minor degrees of hyperthermia will result in worsening of the neurologic injury.

**Blood Pressure Management.** The management of blood pressure in patients with acute ischemic stroke and TIA is controversial because of limited data. Current guidelines for the management of hypertension in patients with acute ischemic stroke recommend that antihypertensive treatment be reserved for those with markedly elevated blood pressures, unless fibrinolytic therapy is planned or specific medical indications are present. These medical indications include (1) acute myocardial infarction, (2) aortic dissection, (3) true hypertensive encephalopathy, and (4) severe left ventricular failure.

Oral or parenteral agents should be withheld unless the patient’s systolic pressure is greater than 220 mm Hg or diastolic pressure is greater than 120 mm Hg or mean arterial pressure is greater than 130 mm Hg (Table 99-4). If parenteral agents are used, labetalol or enalapril is favored because of ease of titration and limited effect on cerebral blood vessels. Sublingual nifedipine or sublingual nitroglycerin is not recommended because either agent can produce a precipitous drop in blood pressure.

If fibrinolytic therapy is planned, stringent control of blood pressure is indicated to reduce the potential for bleeding after the thrombolytic is administered (see Table 99-4). Thrombolytic therapy is not recommended for patients whose systolic pressure is consistently greater than 185 mm Hg or whose diastolic pressure is 110 mm Hg at the time of treatment. Simple measures can be used to try lowering blood pressure below this level. Recommended approaches include the use of nitroglycerin paste and one or two doses of labetalol, 10 to 20 mg given intravenously. If more aggressive measures are required to reduce blood pressure below 185/110 mm Hg, the use of t-PA is not recommended. Once thrombolytic therapy has been initiated, blood pressure must be monitored closely and hypertension treated aggressively.

Just as problematic as high blood pressure can be, low blood pressure can be quite detrimental to patients with ischemic

*All initial blood pressures should be verified before treatment by repeating reading in 5 minutes.

As estimated by one-third the sum of systolic and double diastolic pressures.

*Labetalol should be avoided in patients with asthma, cardiac failure, or severe abnormalities in cardiac conduction. For refractory hypertension, alternative therapy with sodium nitroprusside or enalapril may be considered.

BP, blood pressure; DBP, diastolic blood pressure; MAP, mean arterial pressure; SBP, systolic blood pressure; TPA, tissue plasminogen activator.

Stroke. Normally normotensive stroke patients with low blood pressure or normally hypertensive stroke patients with low or even low-normal blood pressure should be given a fluid bolus to try to increase cerebral perfusion. This is especially important in patients who present in a dehydrated state. If initial fluid challenge is ineffective, the patient may require vaspressor therapy (e.g., with dopamine) to gradually increase MAP and improve cerebral perfusion.

Acute Drug Therapy. To date, only the use of intravenous t-PA has been approved by the U.S. Food and Drug Administration (FDA) for treatment of patients with acute ischemic stroke. These recommendations initially were based on the results of the National Institute of Neurological Disorders and Stroke (NINDS) trial, although subsequent analysis of other studies has supported its use.78,79 Concern has emerged regarding the safety of the use of t-PA in community practice.74 However, a meta-analysis of non–trial-related use of t-PA in community practice demonstrated efficacy and safety for t-PA similar to those reported in the NINDS trial.75 The current recommendation for recombinant t-PA (rt-PA) is that it be administered intravenously at a dose of 0.9 mg/kg to a maximum of 90 mg (10% of the dose given as a bolus followed by an infusion lasting 60 minutes). Treatment must be initiated within 3 hours of the onset of ischemic symptoms in patients who meet strict inclusion and exclusion criteria (Box 99-4). Intravenous t-PA is not recommended when the time of stroke onset cannot be ascertained reliably, including strokes recognized on awakening. In addition, caution is warranted in treating stroke patients with large strokes (NIHSS score of 20 or higher) or early CT changes from a recent major infarction (e.g., acute hypodensity or mass effect), because they are at increased risk for symptomatic hemorrhage.76 Earlier studies have demonstrated the importance of adhering to the inclusion-exclusion criteria established by the NINDS trial.74 A recent study suggests that patients with mild or rapidly resolving symptoms may still benefit from the use of intravenous t-PA.78 The use of intravenous t-PA beyond the 3-hour window

| **Exclusion Criteria** |
| 1. Evidence of intracranial hemorrhage on noncontrast head CT |
| 2. Only minor or rapidly resolving stroke symptoms |
| 3. High clinical suspicion of subarachnoid hemorrhage even with normal CT findings |
| 4. Active internal bleeding (e.g., gastrointestinal or urinary bleeding within last 21 days) |
| 5. Known bleeding diathesis, including but not limited to: |
|   • Platelet count <100,000/\( \mu \)L |
|   • Patient has received heparin within 48 hours and had an elevated activated partial thromboplastin time (greater than upper limit of normal for laboratory) |
|   • Recent use of anticoagulant (e.g., warfarin sodium) and elevated prothrombin time >15 seconds |
| 6. Within 3 months of intracranial surgery, serious head trauma, or previous stroke |
| 7. Within 14 days of major surgery or serious trauma |
| 8. Recent arterial puncture at noncompressible site |
| 9. Lumbar puncture within 7 days |
| 10. History of intracranial hemorrhage, arteriovenous malformation, or aneurysm |
| 11. Witnessed seizure at stroke onset |
| 12. Recent acute myocardial infarction |
| 13. On repeated measurements, systolic pressure >185 mm Hg or diastolic pressure >110 mm Hg at time of treatment, requiring aggressive treatment to reduce blood pressure to within these limits |

CT, computed tomography.
has not been demonstrated to be of clinical benefit, although a meta-analysis of these studies suggests a beneficial effect in a specific subset of patients. Intra-arterial thrombolysis is an alternative treatment for eligible patients presenting beyond the 3-hour time window but within 6 hours of symptom onset. In the Prolyse in Acute Cerebral Thromboembolism II (PROACT II) study, patients with middle cerebral artery stroke were 58% more likely than those who received a placebo to have little or no neurologic disability at 90 days when treated with prourokinase up to 6 hours after stroke onset. In addition, the use of intra-arterial thrombolysis in patients with posterior circulation strokes and those unresponsive to initial treatment with intravenous t-PA also is being evaluated and has shown favorable outcomes.

A variety of mechanical clot retrieval devices are being investigated. The best studied is the Mechanical Embolus Removal in Cerebral Ischemia (MERCI) retrieval device. This corkscrew-like device has been shown to be successful in recanalizing intracranial lesions of the internal carotid artery and has demonstrated improved clinical outcomes and survival compared with patients without successful recanalization of the artery. Successful recanalization has been achieved when performed within an 8-hour window of symptom onset. In 2004, the FDA cleared the MERCI retrieval device for use in the setting of acute ischemic stroke. Previous studies have focused on the use of antiplatelet agents in acute ischemic stroke. Data from two large trials involving almost 40,000 patients indicate that early use of aspirin in patients with acute ischemic stroke who were not treated with a fibrinolytic agent was associated with a small but significant reduction in rates of stroke recurrence and mortality. These studies in combination suggest a number needed to treat of 77 (i.e., 77 stroke patients would need to be treated with daily aspirin therapy to prevent a poor outcome, such as death, dependency at discharge or at 6 months after stroke, in 1 patient). The need for acute administration of aspirin in the ED is unclear, because patients were given aspirin up to 48 hours after stroke onset. Aspirin should not be given for the first 24 hours in patients who have received a fibrinolytic agent, because this has been associated with an increased risk of ICH and death.

The use of low-molecular-weight or unfractionated heparin is common in patients with acute ischemic stroke or TIs, but its value is unproved. Some studies suggest that heparin may reduce the risk of subsequent ischemic stroke but increase the risk of hemorrhagic stroke. To date, no studies have definitively established the efficacy of anticoagulants in the management of acute ischemic stroke. However, heparin sometimes is considered in patients at high risk for stroke progression, including patients with crescendo TIs or TIA due to a cardioembolic source, patients with a high-grade carotid artery stenosis, patients with posterior circulation TIA, and patients with evolving strokes. Heparin is recommended for the treatment of carotid and vertebral artery dissection unless a contraindication such as intracranial extension is present. If a dissection is diagnosed and the patient has no symptoms of ischemia, treatment with antiplatelet therapy alone may be an option. Heparin therapy should not be initiated in patients with suspected endocarditis or in any patient until a CT scan has ruled out intracranial bleeding. Owing to the lack of consistent evidence of efficacy, the most prudent course in the ED setting is to determine the need for heparin therapy in conjunction with the patient’s neurologist or the admitting physician.

Other innovative approaches to stroke care, including mild to moderate hypothermia and early hemicraniectomy, are currently being investigated.

Management of Intracranial Hemorrhage. The patient with a potential ICH requires rapid assessment and transport to a care center with CT scanning capability and intensive care management facilities. Out-of-hospital management is similar to that for ischemic stroke. The circumstances surrounding the event, as well as other concomitant medical conditions, also should be ascertained. The initial level of consciousness, GCS score, any gross focal deficits, difficulty with speech, clumsiness, gait disturbance, or facial asymmetry should be noted.

Supportive care involving attention to airway management and perfusion is of the highest priority. Patients with hemorrhagic stroke are more likely to have an altered level of consciousness that may rapidly progress to unresponsiveness requiring emergent endotracheal intubation. Intravenous access should be established and cardiac monitoring should be initiated. Evaluation of blood glucose and appropriate dextrose and naloxone administration should be considered in any patient with altered mental status.

Considerable disagreement exists regarding optimal blood pressure management in the patient with ICH. Hypertension may cause deterioration by increasing ICP and potentiating further bleeding from small arteries or arterioles. On the other hand, hypotension may decrease CBF, thereby worsening brain injury. In general, recommendations for treatment of hypertension in patients with ICH are more aggressive than those for patients with ischemic stroke. The current consensus regarding management of ICH is to recommend antihypertensive treatment with parenteral agents for systolic pressures higher than 160 to 180 mm Hg or diastolic pressures higher than 105 mm Hg. Treatment for lower pressures remains controversial. Nitroprusside is the agent most commonly recommended because it can provide rapid and consistent lowering of the blood pressure to the desired level, and adjustments can be rapidly made. Nitroprusside provides a rapid onset, is titratable, and has no effect on mental status. Disadvantages include the need for careful monitoring (ideally with an indwelling arterial catheter) and the theoretical risk of worsening the hemorrhage due to the vasodilatory effects of nitroprusside on cerebral vessels. Labetalol is another therapeutic option. More recently, nicardipine has been proposed as an optimal antihypertensive agent in the setting of cerebrovascular emergencies, owing to both its good titration profile, which may create less need for adjunctive antihypertensive drugs, and its favorable cerebral hemodynamic effects.

Hyperventilation and diuretics such as mannitol have been used when ICH is complicated by signs of progressively increasing ICP, clinical deterioration associated with mass effect, or impending uncal herniation. These interventions should not be used prophylactically. Mannitol moves fluid from the intracranial compartment, thereby reducing cerebral edema. Although this effect may be temporarily helpful in the acute setting, the brain tissue will reequilibrate and rebound swelling can occur and worsen the patient’s clinical status. The effectiveness of mannitol in the setting of ICH is questionable. Hypertonic saline is being investigated as an alternative agent. Use of steroids in cerebral hemorrhage, once a common practice, appears to be harmful and is not recommended. Other experimental modalities include barbiturate coma and hypothermia.

Seizure activity can cause neuronal injury, elevations in ICH, and destabilization of an already critically ill patient. In addition, nonconvulsive seizure may contribute to coma in up to 10% of patients in a neuro–intensive care unit. Seizure prophylaxis (fosphenytoin 18 mg/kg) should be considered for patients with ICH, especially those with lobar hemorrhage. Surgery is not beneficial in most cases of ICH. Selected patients with sizable lobar hemorrhage and progressive neuro-
logic deterioration may benefit from surgical drainage. Surgery is more efficacious in patients with cerebellar hemorrhage. The clinical course in cerebellar hemorrhage is notoriously unpredictable. Patients with minimal abnormalities may experience sudden deterioration, with progression to coma and death, with little warning. For this reason, most neurosurgeons will consider emergent surgery for patients with cerebellar hemorrhage within 48 hours of onset. In cases of severe intraventricular hemorrhage or hematomas in the posterior fossae, the normal circulation of cerebrospinal fluid (CSF) can become interrupted, leading to the development of hydrocephalus. This condition is characterized by an abnormal rise in CSF volume. In such cases a ventricular catheter should be inserted by a neurosurgeon.

**DISPOSITION**

**Ischemic Stroke and Transient Ischemic Attacks**

“Stroke center” definitions have been proposed, and a national certification process for primary stroke centers is now under way despite considerable political controversy. In broad terms, institutional certification as a primary stroke center requires the establishment of a stroke infrastructure (such as a stroke team, stroke unit, patient care protocols, and support services including CT scanning and laboratory testing availability), as well as institutional administrative support and strong leadership.

Additionally, recommendations also have been established for comprehensive stroke centers (CSCs). CSCs are expected to have the capability to provide the full spectrum of care to patients with stroke and other cerebrovascular diseases. More specifically, CSCs should offer advanced imaging modalities, perform surgical and endovascular interventions, and maintain a core infrastructure such as a stroke unit and stroke registry. The establishment of PSCs and CSCs is expected to have the capability to provide the full spectrum of care to patients with stroke and other cerebrovascular diseases. More specifically, CSCs should offer advanced imaging modalities, perform surgical and endovascular interventions, and maintain a core infrastructure such as a stroke unit and stroke registry. The ABCD (age, blood pressure, clinical features, duration of TIA symptoms) score has been validated as a good predictor of future stroke risk in patients with TIA treated in the ED. ABCD scores range from 0 to 6, with a higher score indicating a higher future stroke risk; this scoring system is based on the following criteria: age 60 years or older = 1 point; systolic blood pressure greater than 140 mm Hg and/or diastolic greater than 90 mm Hg = 1 point; unilateral weakness = 2 points; speech disturbance without weakness = 1 point; symptom duration 10 to 59 minutes = 1 point; symptom duration 60 minutes or longer = 5 points. Patients with an ABCD score of 5 or 6 in the ED have a 30-day risk of stroke eight times that of patients with an ABCD score less than 5 (hazard ratio 8.01; 95% CI: 3.21 to 19.98).

**Hemorrhagic Stroke**

All patients with an acute hemorrhagic stroke in whom surgical intervention is a consideration should be admitted to an intensive care unit under the care of a neurologist or a neurosurgeon. If this is unavailable at the evaluating institution, the patient should be transported to an appropriate institution.

**Acknowledgment**

The authors gratefully acknowledge the assistance of Stephen M. Davis, MPA, MSW, Co-Director of Clinical Research at the West Virginia University Department of Emergency Medicine, in the preparation of this chapter.
### KEY CONCEPTS

- Patients presenting with the signs and symptoms of an acute ischemic stroke within 3 hours of symptom onset should be evaluated for thrombolytic therapy within the NINDS-recommended time frames (see Table 99-3).
- Carotid Doppler, MRA, or CTA studies are recommended before discharge of a patient with TIA from the ED.
- Overly aggressive blood pressure management should be avoided in patients with acute ischemic stroke.
- Accurate time of symptom onset should be documented in all patients with stroke.
- Assessment of gait is essential to rule out posterior circulation stroke in patients presenting with vertigo.
- The possibility of carotid or vertebral dissection should be considered in young patients with stroke and in patients with headaches and neck pain with acute stroke.

**CHAPTER 100  Seizures**

*Evelyn H. Duvivier and Charles V. Pollack, Jr.*

---

**PERSPECTIVE**

A *seizure* is the clinical manifestation of excessive, abnormal cortical neuron activity. The physical manifestation depends on the area of brain cortex involved and, to a lesser extent, on the specific underlying abnormality. Patients who have recurring seizures without consistent provocation have *epilepsy*, although this term encompasses many disparate clinical syndromes. Seizures also may occur as a predictable response to certain toxic, pathophysiologic, or environmental stresses; these are *reactive or secondary seizures*, and patients who experience them do not have epilepsy. In the United States, 10% of people experience at least one seizure in their lifetime; the cumulative incidence of epilepsy is 3%.1

The evaluation of patients with seizures, whether ongoing or recent, in the emergency department (ED) may be complex and difficult. A careful history must be elicited to determine the presence of ictal events that represent epilepsy or exposure to ictogenic stimuli (e.g., alcohol, cocaine), significant underlying illness (e.g., meningitis, hypoxemia, hypoglycemia, intracranial mass), or contributing causes (e.g., sleep deprivation in an epileptic). The physical examination should focus on the identification of focal neurologic abnormalities, systemic illness, and signs of toxic exposure. If the patient continues to experience seizure activity, airway protection and abortive therapy must be provided. Laboratory and radiographic evaluation that is guided by historical and physical findings may be limited or unnecessary in some cases. Finally, the appropriate disposition of a patient presenting to the ED with a seizure or with a history of recent seizure requires an understanding of the underlying illness, likelihood of recurrence, indications for maintenance pharmacologic therapy, and state reporting regulations.

In addition to the distinction between primary (epileptic) and secondary (reactive) seizures, many other classifications of ictal events have been proposed.2-7 Seizures are termed *generalized* or *focal (partial)* depending on their clinical manifestations. The former type of seizure results from the abnormal electrical event that simultaneously involves both cerebral hemispheres and is accompanied by loss of consciousness; in the latter, abnormal activity is limited to part of one cerebral hemisphere only. Generalized seizures usually are characterized by rhythmic, tonic-clonic muscle contractions, or *convulsions*, although *nonconvulsive generalized seizures* also occur. Partial seizures can be differentiated further into seizures during which cognition is maintained (*simple partial*) and seizures during which cognition is impaired (*complex partial*). The term *cognition* is defined as involving at least two of the five features—perception, attention, emotion, memory, and executive function— and replaces the previously used term *consciousness*, which is both difficult to define and difficult to document. Finally, partial seizures may become generalized (*partial with secondary generalization*).

Inexperienced witnesses may provide histories that are insufficient for accurate categorization of seizures. However, when an accurate history is available, secondary (reactive) seizures typically are generalized, not partial, in nature. The definitive differentiation among these classifications may require electroencephalogram (EEG) recording during the seizure, sometimes in association with simultaneous video recording.

Seizures in children, as in adults, are classified as primary (idiopathic) and secondary (symptomatic or reactive). The term *cryptogenic* is used sometimes when seizures are thought to be secondary but no cause has been identified. The history is the most important diagnostic tool in evaluating seizures in children. The actual seizure activity usually is not observed, and the emergency physician must rely on a detailed and accurate history for diagnosis.

Other important terms to describe ictal events include *status epilepticus*, in which seizures occur serially without an intervening return to a normal neurologic condition; *spasm*, which is a specific, debilitating seizure syndrome that occurs in infants; and *myoclonus*, which refers to rhythmic, shock-like muscle contractions also typical for specific seizure syndromes. The *postictal period* is an interval after a seizure, of variable duration, usually characterized by impaired consciousness but sometimes also marked by self-limited focal paralysis or neurogenic pulmonary edema.

---

**PRINCIPLES OF DISEASE**

The pathophysiology of seizures at the neuronal level is incompletely understood, with most of what is known coming from animal studies in which either electrical or pharmacologic stimulation is applied directly to brain cortex. To produce generalized ictus, stimuli must be applied to both hemispheres simultaneously. Some studies show the concept of recruitment, which occurs when the initiating neurons’ abnormal, increased electrical activity activates adjacent neurons and propagates until the thalamus and other subcortical structures are recruited. The clinical seizure activity typically, but not always, reflects the focus of initiation.9-11
What prompts such initiation is unclear. Proposed mechanisms include disruption of normal structure—whether congenital, maturational, or acquired (as with scar tissue)—and disruption of local metabolic or biochemical function. The latter mechanism is better elucidated because the roles of two neurotransmitters—acetylcholine, which is excitatory to cortical neurons, and γ-aminobutyric acid (GABA), which is inhibitory—have been more fully characterized. In sensitive neurons, such as those at an ictogenic focus, subtle changes in the local concentrations of these neurotransmitters can produce sustained membrane depolarization, ultimately followed by local hyperpolarization and recruitment. Recruitment may follow contiguous paths or extend along diverse integrated circuits that are deep and cross the midline.9,11

When the ictal discharge extends below the cortex to deeper structures, the reticular activating system in the brainstem may be affected, altering consciousness. In generalized seizures, the focus often is subcortical and midline, which explains the prompt loss of consciousness and bilateral involvement.9,12 Seizures typically are self-limited; at some point, the hyperpolarization subsides, and the electrical discharges from the focus terminate. This termination may be related to reflex inhibition, loss of synchrony, neuronal exhaustion, or alteration of the local balance of acetylcholine and GABA in favor of inhibition.9,12

The systemic manifestations of convulsive ictal activity include hypertension, tachycardia, tachypnea, and hyperglycemia from sympathetic stimulation. With more prolonged convulsions, skeletal muscle damage, lactic acidosis, and, rarely, frank rhabdomyolysis may ensue.9,10,13 Autonomic discharge and bulbar muscle involvement may result in urinary or fecal incontinence, vomiting (with significant aspiration risk), tongue biting, and airway impairment.

**CLINICAL FEATURES**

**Primary Seizures in Adults**

Primary ictal events in adults include events of genetic and of idiopathic origin. Onset is typically during childhood or adolescence, but occasionally idiopathic seizures may begin de novo in adulthood. Because idiopathic seizures are rare, a first-time seizure in an adult requires a thorough ED evaluation.

**Focal seizures** in adults may be classified as simple partial or complex partial. Simple partial seizures are limited in electrical focus to one cerebral hemisphere and do not cause loss of cognition. Although the specific function of the initiating neurons determines the clinical manifestation of the ictal event (i.e., motor, somatosensory, special sensory, autonomic, or psychic), such clinical manifestations are not sufficiently specific for anatomic localization without an EEG. Typical features of simple partial seizures include focal clonic movements; paresthesias; visual, auditory, olfactory, or gustatory experiences; sweating and flushing; dysphasia; a sense of déjà vu; or a sense of unwarranted fear.9,17 Motor signs, which by definition remain ipsilateral in simple partial seizures, may spread continguously in a stepwise fashion (Jacksonian march) as neuron recruitment occurs in the motor cortex. There is generally no postictal state after a simple partial seizure.

**Complex partial seizures** are ictal events that involve impairment of cognition, either at onset or evolving from focal activity. Amnesia for the ictal event is a consistent feature of complex partial seizures, although during the episode the patient may remain responsive to the surroundings. Complex partial seizures typically involve automatisms that are specific to the affected person, such as lip smacking, repeated swallowing or uttering verbal phrases, or picking at clothing. Complex partial seizures generally are associated with an aura, such as a specific smell, taste, visual hallucination, or intense emotional feeling. In contrast with those experiencing generalized seizures, these patients may continue with ongoing motor activity, such as driving an automobile, riding a bicycle, or playing a musical instrument (reactive automatisms), and they may react to their surroundings in a semiaappropriate manner.7 Partial seizures may progress rapidly to generalized seizures. A postictal state is common after complex partial seizures and may persist for hours.9,11

**Generalized seizures** in adults may be convulsive or nonconvulsive. By definition, patients lose consciousness in a generalized seizure, and no aura is present. Some patients may experience a brief, vague prodrome or dysphoric state just before the ictal event. Convulsive generalized seizures are typified by the tonic-clonic, or grand mal, seizure, in which the patient loses consciousness, stiffens with generalized muscular hypertonus, and then rhythmically and violently contracts multiple, bilateral, and usually symmetrical muscle groups. The muscular force may be sufficiently vigorous to result in posterior shoulder dislocation or fractures of thoracic spine vertebral bodies; significant tongue and buccal injuries also may be incurred from biting with repeated jaw muscle contractions. Dysautonomia, including transient apnea, is a potential manifestation of convulsive generalized seizures; urinary incontinence is more common than fecal incontinence. A generalized convulsive seizure generally lasts 1 to 2 minutes and is followed by a postictal state, headache, and drowsiness that may persist for hours. This state must be differentiated in the ED from altered consciousness attributable to other causes.

**Nonconvulsive generalized seizures** include absence, or petit mal, seizures; myoclonic seizures; tonic seizures; and atonic seizures. Absence seizures in adults are subclassified further as typical or atypical. Typical absence ictus is characterized by the sudden cessation of normal, conscious activity followed by a nonconvulsive, dissociative state that persists for a few seconds to several minutes before suddenly terminating. Eye movements, blinking, or automatisms may be present. There is no aura and no postictal state. If the seizure occurs midsequence, then the patient typically will resume speaking at precisely the point of interruption without awareness of the intervening event. Absence seizures typically begin in childhood but occasionally develop in adults. Atypical absence seizures are marked by more complicated motor signs, coexistence with other forms of generalized seizures, inconsistent postictal confusion, and irregular EEG abnormalities.9,11

**Atonic seizures** are characterized by focal diminution of muscle tone (limb or head) or generalized loss of postural tone in which the head falls forward and then the body slumps to the ground (“drop attack”), usually landing buttocks first (although this can vary depending on the axis of gravity at the time of the fall). Recovery occurs immediately, and there is either no loss or an extremely brief loss of consciousness. In myoclonic-atonic seizures, a brief (less than 100 msec) myoclonic jerk of muscle group of variable anatomy occurs before the episode of atonia.9 Because typically no postictal state is associated with these episodes, an altered level of consciousness in a patient presenting to the ED after an atonic or myoclonic-atonic seizure should prompt an investigation for head trauma or a toxic or metabolic abnormality.

**Status epilepticus** is defined as serial seizure activity without interictal recovery or prolonged, continuous seizure activity. Traditionally, status epilepticus was defined as seizure activity lasting longer than 30 minutes, which is the estimated duration necessary for neuronal injury.9,11 However, because an isolated tonic-clonic seizure rarely lasts more than a few minutes, an operational definition of status epilepticus has been
advocated as either a continuous seizure lasting more than 5 minutes, or more than two discrete seizures without intervening recovery of consciousness. Although it is recognized that the underlying cause of status epilepticus is the predominant factor determining morbidity and mortality, prolonged seizure activity does cause neuronal injury and therefore warrants prompt abortive therapy. Furthermore, status epilepticus may become refractory to treatment over time.14,17

The most common cause of status epilepticus is discontinuation of anticonvulsant medication. This situation may be compounded by barbiturate withdrawal when phenobarbital therapy is abruptly withdrawn. Patients may present for the first time with a primary seizure disorder in status. Many other causes of status epilepticus have been documented9,15,18,19 (Box 100-1). After prolonged status epilepticus or after incomplete treatment, the patient may exhibit very subtle manifestations of continued seizure activity, such as small-amplitude twitching of the extremities or jerking of the eyes, or any visible motor activity may cease while seizure activity detectable on the EEG continues.9,20-22 Recognition of the latter scenario, termed nonconvulsive status epilepticus, requires a high index of clinical suspicion. Prompt treatment is essential; otherwise, neuronal damage can result.

All classes of primary seizures may recur sporadically, randomly, or predictably. Cyclic recurrence has been reported with awakening, sleep deprivation, emotional or physical stress, alcohol, and menses, among other factors. Seizures also may be triggered by specific sensory stimuli, the most common of which is visual stimulation in the form of flashing lights, such as strobe lights, television, and video games.9,23 Seizures also can be caused by auditory, gustatory, tactile, or startle triggers that are specific to the affected person. The most common cause of recurrent primary seizures is medication noncompliance.9,11

Reactive Seizures in Adults

Reactive or secondary seizures do not result from genetic or idiopathic causes. The conditions that cause reactive seizures may be static (e.g., anatomic scarring), progressive (e.g., degenerative cortical disorders), or transient (e.g., acute electrolyte derangements).

Seizures Caused by Metabolic Derangements

Hypoglycemia is a common metabolic cause of reactive seizures. Ictal activity can occur when the plasma glucose level is less than 45 mg/dL, although some patients may manifest neurologic disturbances even at higher levels.24 A rapid bedside glucose test should be an integral part of the ED evaluation of the patient exhibiting seizure activity. Convulsive and nonconvulsive seizures and generalized and partial seizures all may occur during hypoglycemia.24 Patients at the extremes of age are particularly susceptible to glucose stress during acute illness. Hypoglycemia also may result from insulin reaction, a deliberate insulin or hypoglycemic agent overdose, alcoholism, poor nutrition, and sepsis. Hypoglycemic seizures respond to glucose therapy; anticonvulsants are unnecessary.

Cation derangements, notably hyper- and hyponatremia, hypomagnesemia, and hypocalcemia, are other common metabolic causes of ictal activity.25,26 Hypo-osmolar and hyperosmolar states can precipitate seizures. Disorders of sodium—the primary cation in the extracellular fluid compartment and the primary determinant of serum osmolarity—are most common. Hyponatremia is the most frequently identified electrolyte disorder in hospitalized patients, and sodium levels less than 120 mEq/L often are associated with seizures.27,28 The rate at which the sodium level decreases, and not the absolute magnitude of the decrease, determines the risk for neurologic manifestation.27,29 Correcting hyponatremia should be undertaken slowly in the ED, to avoid osmotic demyelination. If seizures are persistent, administration of hypertonic (3%) saline may be indicated.27 Hypernatremia will result in cerebral edema and seizures in the setting of rapid elevation of serum sodium to greater than 160 mEq/L, or during aggressive correction of subacute hyponatremia.25,26

Hypocalcemia reduces neuronal excitability and rarely causes seizures; significant hypocalcemia (7.5 mEq/L) is associated, however, with ictal activity. Hypocalcemia may result
from hypoparathyroidism, renal failure, or acute pancreatitis and typically is associated with hypomagnesemia, which also can precipitate seizures, particularly at serum levels less than 1 mEq/L. Hypomagnesemia is seen most often as a result of poor nutrition, especially in alcoholic patients. Patients with significant hypomagnesemia or hypocalcemia should be treated empirically for both disorders.25,26

Nonketotic hyperosmolar hyperglycemia also is associated with seizure activity. Partial seizures, including partial status, predominate. These seizures do not respond to anticonvulsants; rather, they are best managed with gradual correction of fluid deficits and glucose excess.30,32

Seizures may complicate the course and treatment of renal failure.33 Ictal activity occasionally complicates uremic encephalopathy, is more common in conjunction with acute fluid and electrolyte shifts during dialysis (dialysis disequilibrium syndrome), and can occur as a complication of immunosuppressive therapy after renal transplantation.

Thyroid hormones lower seizure threshold, and consequently Graves’ disease and thyrotoxicosis may occasionally manifest as seizures, including status epilepticus.9,34,35 Seizures also occur with hypoparathyroidism as a direct result of secondary hypocalcemia.36

Seizures Caused by Infectious Diseases

Infectious diseases can cause seizures independent of a purely febrile mechanism. These seizures generally result from primary central nervous system (CNS) infections but occasionally arise from other septic sources. The most important ictogenic infections are meningitis, encephalitis, cerebral abscess, cerebral parasitosis, and human immunodeficiency virus (HIV) disease and associated opportunistic infections, with their protean CNS manifestations.

Seizures can occur as a result of the acute inflammatory response or as sequelae to bacterial or viral meningitis. During the acute course of their illness, up to 40% of patients with meningitis will have at least one seizure; this is more common at the extremes of age but is rarely associated with residual epilepsy.9,37,38 By contrast, seizures occur in up to 50% of patients with a brain abscess, and epilepsy develops in 40% of the survivors.9,39 After meningitic seizures are terminated with benzodiazepines, phenytoin should be initiated temporarily.7

Viral meningoencephalitides, the most common of which are caused by the herpes simplex virus, also are associated with seizures. These seizures may be generalized or partial, often recur during the acute phase of the illness, and may persist after the illness resolves.9

The parasitic CNS infection neurocysticercosis is relatively common in areas of the United States in which the population includes immigrants from Latin America. Seizures complicate 50 to 90% of neurocysticercosis cases.40 Latent syphilis also may be a cause of adult-onset seizures. Primary HIV disease of the CNS, its attendant infectious and mass lesion complications, such as from toxoplasmosis and lymphoma, and the demyelinating infection progressive multifocal leukoencephalopathy constitute a significant cause of generalized and partial seizures.41 Choosing an antiepileptic drug for an HIV-infected patient with seizures should be done in consultation with infectious disease and neurology specialists, because of the well-recognized increase in adverse effects of and interactions between antiepileptic drugs and antiviral medications.

Seizures Caused by Drugs and Toxins

The list of substances reported to cause seizures either as an idiosyncratic side effect of therapeutic use or as a manifestation of toxic overdose is extensive.18,42 The recognition of this etiologic category is crucial in the ED setting. Seizure activity should be viewed as a dire sign of toxicity and may herald the onset of life-threatening instability.

Seizures may occur after therapeutic doses of antimicrobials, cardiovascular agents, neuroleptics, and sympathomimetics.43 Seizures also may result from exposure to plant toxins, insecticides and rodenticides, and hydrocarbons. Certain over-the-counter supplements also have been associated with seizures, either alone or through adverse interactions with prescription medications.44,45 The most common drug-associated and toxin-associated seizures occur, however, in conjunction with illicit drugs, such as cocaine, amphetamines, and phencyclidine; with overdoses of anticholinergic agents, such as cyclic antidepressants and antihistamines; as a manifestation of withdrawal from ethyl alcohol and sedative-hypnotics; and with toxic levels and deliberate overdoses of diverse medications including aspirin, theophylline, meperidine, isoniazid, lithium, and the anticonvulsants phenytoin and carbamazepine.42,46 Standard ED therapeutic measures usually are effective for management of toxic seizures. In some cases, specific antidotal therapy is available, such as alkalization for cyclic antidepressant and salicylate overdoses, pyridoxine (vitamin B6) for isoniazid overdose, and hemodialysis for salicylate and lithium toxicity.

Because of its prevalence in urban ED patient populations, cocaine toxicity warrants special mention.47 Seizures may occur after isolated recreational use or chronic abuse, after overdose, and in “body packers” and “body stuffers.”48 Cocaine-related seizures may be a manifestation of direct CNS toxicity or an indirect result of hypoxia from cardiac toxicity.49 Seizures in cocaine-intoxicated patients must be managed as part of the overall toxic reaction, which often includes high fever, rhabdomyolysis, and cardiac arrhythmias. A benzodiazepine is the appropriate initial therapeutic agent.

Ethyl alcohol is another common toxic cause of seizures. Ictal events may occur with acute inebriation but are more common during withdrawal from alcohol.50 Withdrawal seizures typically are generalized, are recurrent, and may begin within 6 hours of cessation of or decrease in alcohol consumption. Through a phenomenon termed kindling, the risk and severity of seizures increase with each episode of withdrawal. Kindling implies that with each episode of alcohol withdrawal, the seizure threshold is lower. Alcoholic patients with seizures must be evaluated for other related, concomitant ictogenic problems (e.g., hypoglycemia, electrolyte derangements, head trauma, co-ingestion of other toxins, pregnancy). The preferred treatment for alcohol-associated seizures is with benzodiazepines; these drugs substitute for the GABA-enhancing effect of ethanol in the CNS.

Seizures Caused by Trauma

Post-traumatic seizures can occur acutely as a result of blunt or penetrating head trauma or as a post-traumatic sequel. Immediate post-traumatic seizures occur within 24 hours of injury. Epidural, subdural, and intracerebral hematomas and traumatic subarachnoid hemorrhages all can be acutely ictogenic, particularly as intracranial pressure rises. More often, however, the onset of seizure activity is delayed for at least several hours. Early post-traumatic seizures occur within 1 week of injury, whereas late post-traumatic seizures occur after 1 week. Immediate and early post-traumatic seizures are more common in children than in adults, and children also are more likely than adults to present in status epilepticus in the immediate or early post-traumatic phase.51,52 Within the first year after significant head trauma, the incidence of seizures is at least 12 times that in the general population.53
Seizures Associated with Malignancy or Vasculitis

Seizures are a common manifestation of primary and metastatic CNS neoplasms. They also may complicate cancer treatment as a result of postsurgical scarring or chemotherapy-related electrolyte derangements, hematologic abnormalities, or immunosuppression. Although any CNS tumor can be ictogenic, low-grade and slow-growing primary neoplasms (e.g., well-differentiated gliomas and oligodendrogliomas) are implicated most commonly.57 In such cases, seizures, which most often are partial with secondary generalization, may be the initial clinical manifestation. A new-onset seizure in a patient with a non-CNS primary malignancy, such as melanoma and tumors of the lung, breast, colon, germ cells, or renal cells, should prompt consideration of CNS metastasis and warrants neuroimaging.

Seizures also may be the presenting manifestation of CNS vasculitis in patients with systemic lupus erythematosus and polyarteritis nodosa. These commonly are complex partial seizures that give a general indication of the acute inflammatory focus. Sometimes secondary generalization follows.38

Seizures Caused by Strokes, Arteriovenous Malformations, and Migraines

Ischemic or hemorrhagic stroke is the cause of new-onset seizures in 40 to 54% of elderly patients.59 The overall incidence of seizures with stroke ranges from 4 to 15%; more than one half occur within the first week after stroke. The incidence of epilepsy after stroke is 4 to 9%.60,61 Seizures that occur acutely with stroke are thought to result from local metabolic alterations in the CNS; these events are transient, and the seizures often are focal and self-limited. Seizures that develop later are more likely to be generalized.

Seizures also occur in conjunction with unruptured cerebrovascular aneurysms and arteriovenous malformations.7 Arteriography may be required to confirm the diagnosis; unruptured arteriovenous malformations are easier to detect on an enhanced cranial computed tomography (CT) scan than are smaller, unruptured aneurysms. Seizures also may arise in concert with vascular headaches, either coincidentally, by migrainous activation of an epileptic focus, or after vascular headache has induced cerebral infarction that becomes an epileptic focus.82

Seizures Caused by Degenerative Disease of the Central Nervous System

In approximately 5% of patients with multiple sclerosis, focal or generalized seizures develop during the course of their illness. These seizures must be differentiated from the tonic spasms that may occur in multiple sclerosis. Patients with demyelinating disease also should be evaluated for the other types of reactive seizures.9

The severity of head injury correlates with the likelihood of post-traumatic seizures. The incidence of seizures after injury with neurologic deficit without dural violation is 7 to 39%; when the dura is disrupted, the incidence is 20 to 57%.53 Imaging studies should be performed urgently because the likelihood of identifying significant cerebral edema, cerebral contusions, hematomas, and depressed skull fractures is relatively high.52,54 Antiepileptic drugs are recommended for prophylaxis against post-traumatic seizures occurring within the first 7 days after severe brain injury in adults; however, they have not been shown to be effective in preventing late post-traumatic seizures.51,55,56

Strokes, Arteriovenous Malformations, and Migraines

Seizures associated with pregnancy are divided into two categories: gestational epilepsy, in which hormonal and metabolic changes exacerbate underlying epilepsy or adversely influence serum levels of anticonvulsants, and eclampsia or toxemia, which is a gestational hypertensive encephalopathy manifested by seizures, hypertension, coma, proteinuria, and edema. For the former, antiepileptic therapy should be tailored by the patient’s neurologist and obstetrician to maximize seizure control and minimize the risk of teratogenic effects.64 Convulsive generalized status epilepticus in pregnancy jeopardizes both mother and fetus. The definitive treatment for eclamptic seizures is magnesium sulfate. Simultaneous reduction in blood pressure using hydralazine, labetalol, or nifedipine is recommended.65

Psychogenic Nongeographic Seizures

Psychogenic seizures, or pseudoseizures, are functional events that may be associated with alterations in consciousness, abnormal movements and behaviors, and autonomic changes. They are not the result of abnormal CNS electrical activity. Psychogenic seizures may be primarily motor and mimic convulsive generalized seizures, including refractory status epilepticus, or they may be nonconvulsive and mimic either absence or complex partial seizures. Although certain features of convulsive psychogenic seizures may suggest the diagnosis, no clinical criteria are 100% specific; simultaneous video and EEG recordings may be required to confirm the diagnosis.9

The ED evaluation of these patients is difficult, because seizures and pseudoseizures can coexist. All but obviously functional abnormalities should be treated as for true ictus pending formal neurologic evaluation. Many patients with pseudoseizures are not deliberately attempting to mislead the examining physician. The long-term treatment of patients with confirmed pseudoseizures may include direct confrontation, intensive psychotherapy, and a placebo.

Postictal States

The postictal state that follows most generalized seizures typically is characterized by a decreased level of arousal and responsiveness, disorientation, amnesia, and headache. These conditions may persist for only a few minutes or for many hours and may not be consistent from seizure to seizure. The most important consideration in ED management of the postictal state is to monitor and investigate the altered mental status after a seizure; otherwise, dangerous underlying metabolic or toxic abnormalities may be overlooked. At the minimum, airway positioning maneuvers, pulse oximetry, rapid glucose determination, and cardiac rhythm monitoring are necessary.

Two unusual postictal manifestations may provoke particular consternation in the ED: postictal paralysis and neurogenic pulmonary edema. Postictal paralysis, or Todd’s paralysis, may
follow generalized or complex partial seizures and is a focal motor deficit that may persist up to 24 hours. Weakness of one extremity or a complete hemiparesis may occur; in the latter case, the patient must be safely restrained to avoid falls caused by a combination of weakness and diminished responsiveness resulting from the postictal state. Todd’s paralysis is associated with a high likelihood of an underlying structural cause for the seizure.

Neurogenic pulmonary edema is a relatively common, although often subclinical, complication of any structural CNS insult, including seizure, trauma, and hemorrhage. Neurogenic pulmonary edema probably is caused by centrally mediated sympathetic discharge and generalized vasoconstriction, coupled with increased pulmonary capillary membrane permeability. After a seizure, neurogenic pulmonary edema can be confused clinically and radiographically with aspiration pneumonia. Neurogenic pulmonary edema is managed with ventilatory support, including positive end-expiratory pressure and other aggressive measures to reduce intracranial pressure. Hypoxia or other clinical evidence of pulmonary congestion after a seizure should prompt consideration of neurogenic pulmonary edema.

## Diagnostic Strategies

### First-Time Seizures

The essential components of the seizure evaluation in the ED setting are discussed in Chapter 16. An accurate and thorough history of the ictal event, any known or potential precipitants or exposures, and the patient’s medical problems must be obtained. A thorough physical examination, including a complete neurologic examination, is essential. Any identified focal neurologic deficits must be monitored for progression or resolution. Appropriate ancillary studies may be comprehensive, but if precipitants (e.g., hypoglycemia, intoxication) are known, studies may be comparatively limited. Although the Academy of Neurology recommends neuroimaging, by either CT or magnetic resonance imaging (MRI), for all adults presenting with an apparent unprovoked first seizure, the usefulness of emergent imaging depends on the clinical situation.

An emergent cranial CT scan is indicated when a serious structural lesion is suspected on clinical grounds, including presence of a new focal deficit, persistent altered mental status, fever, recent trauma, persistent headache, history of cancer, anticoagulant use, suspicion or known history of AIDS, age older than 40 years, and partial-complex seizure. A reasonable approach may be to obtain scans on an outpatient, follow-up basis in patients who have recovered completely from the ictal event and in whom no apparent cause has been elucidated; if reliable follow-up care is unlikely or even questionable, the CT scan should be obtained in the ED to ensure its completion. In patients with known epilepsy and recurrent seizures, the same considerations apply, but in addition, epileptic patients with a change in seizure pattern, prolonged postictal state, or persistent abnormal mental status should be scanned in the ED.

The decision to initiate anticonvulsant therapy after a single seizure depends on the etiology of the seizure. Seizures due to structural lesions, such as stroke, tumor, or head injury, are likely to recur and may warrant antiepileptic medication. However, such patients also are likely to be admitted to the hospital if the lesion is newly discovered. For patients with a single unprovoked seizure, most authorities now agree that antiepileptic therapy should not be initiated; rather, the patient should be discharged with referral for neurologic consultation. The rationale for this approach is threefold. First, the diagnosis may be incorrect, especially if the seizure-like activity was not witnessed by ED personnel. It is estimated that 20 to 25% of patients diagnosed as having seizures are found to have been misdiagnosed, with the most frequent alternative diagnoses being cardiovascular and psychopathologic. Second, the patient may not have a recurrent seizure. It is estimated that less than 50% of patients who have had a single unprovoked seizure will experience a recurrent seizure within 2 years. Furthermore, whereas treatment decreases the risk of early recurrent seizure, it does not affect long-term prognosis of epilepsy, nor does it have an impact on patient quality of life, with the exception of driving limitations, which are prolonged in a patient with a recurrent seizure. Third, antiepileptic medications have side effects that may outweigh the benefit of treatment, especially in women of childbearing age, owing to the teratogenic risk of antiepileptic drugs, and in patients with liver, kidney, or hematologic disorders and patients already receiving multiple medications.

### Recurrent Seizures

The initial approach to stabilization of a patient with a known seizure disorder does not differ from that for a new-onset patient; this includes a rapid blood glucose determination. The most common cause of seizures in a patient with a diagnosed seizure disorder is noncompliance with medications. However, supratherapeutic and toxic levels of some anticonvulsants, such as carbamazepine, phenytoin, and lamotrigine, whether attained chronically or after acute overdose, can also cause seizures. Accordingly, it is prudent to check the serum drug level, if this test is available, before giving a full loading dose of anticonvulsants to patients on long-term therapy. Meanwhile, a thorough history and physical examination should focus on intercurrent illness or trauma, drug or alcohol use, potential adverse drug-drug interactions with anticonvulsants, a recent change in anticonvulsant dosing regimens, and any change in ictal pattern or characteristics. Clinical indications should dictate the selection of other laboratory or radiographic tests.

### Differential Considerations

Even when a “seizure” is witnessed in the ED, other abnormal movements and states of consciousness can be confused with ictal activity. The most common misdiagnoses are cardiovascular (syncope) and psychogenic, but other considerations in the differential diagnosis include hyperventilation and breath-holding, certain toxic and metabolic states, transient ischemic attacks, narcolepsy, and some movement disorders. Syncope—whether vasodepressive (e.g., “vagal” or micturition syncope), orthostatic, or arrhythmogenic (e.g., paroxysmal ventricular tachycardia or fibrillation, long Q-T syndrome)—may be confused with ictal events; differentiating among these may be particularly difficult when episodes are recurrent—hence the consideration “fit versus faint.” Generally, ictal tonic-clonic movements are much more forceful and are more prolonged than the “twitches” sometimes associated with fainting. In addition, most seizures are characterized by a postictal state, which, with the important exception of atomic drop attack ictus, is not a feature of syncope. The cause of an unwitnessed, unprovoked loss of consciousness with a fall, after which the patient presents to the ED, may be difficult to classify. Retrograde amnesia suggests an ictal diagnosis. Hyperventilation syndrome can be associated with mood disturbances, paresthesias, and posturing movements of the distal extremities. Manifestations of toxic and metabolic disorders...
that may mimic ictus include delirium tremens and alcoholic blackouts, the alteration in consciousness associated with hypoglycemia and acute intermittent porphyria, the buccolingual spasms of phenycyclidine intoxication, and the tonic spasms caused by tetanus, strychnine, and camphor. Nonictal CNS events, such as transient ischemic attacks, transient global amnesia, and atypical migraines, may manifest in a manner similar to that in absence seizures and postictal states such as Todd’s paralysis. Carotid sinus hypersensitivity, which can even result from a too-tight necktie, may cause drop attacks.

Narcolepsy (recurrent irresistible daytime sleepiness), especially when it occurs with cataplexy (sudden falls), may be associated with hallucinations and abnormal movements. It can be differentiated from seizure activity by the history and response to stimulation. Movement disorders, such as hemiballismus and tics, usually are associated with other neurologic problems. Finally, dissociative states such as fugue may be associated with hallucinations and abnormal movements. An EEG is an appropriate diagnostic option in unclear cases.

**Management**

**Immediate Management**

ED management of a patient experiencing a seizure begins with active, anticipatory airway management. In generalized ictus, the gag reflex is suppressed, and vomiting often is complicated by aspiration of gastric contents. The patient should be placed in a left lateral decubitus position, and any dentures should be removed. A bite-block should be placed to protect the tongue and allow access for suctioning.

If the patient is persistently apneic or if an unavailable airway threat is present, endotracheal intubation is warranted for definitive protection. A benzodiazepine should be used as an induction agent in the hope that its action may terminate the seizure or obviate the need for tracheal intubation. Trismus may necessitate use of a short-acting neuromuscular blocking agent to facilitate intubation.

In general, the first-line pharmacologic agent for treatment of any active seizure is a parenteral benzodiazepine. Because benzodiazepines directly enhance GABA-mediated neuronal inhibition, they affect clinical and electrical manifestations of seizures. Benzodiazepines are effective in terminating ictal activity in a majority of patients and have been shown to be more effective than phenytoin in terminating status epilepticus. Although phenobarbital appears to be as effective as the benzodiazepine lorazepam in terminating status epilepticus, the associated high risk of hypventilation and hypotenpsion limits its use as a first-line agent.

Benzodiazepines available in the ED setting include diazepam (Valium), lorazepam (Ativan), and midazolam (Versed) (Table 100-1). All three may be used in patients of any age, and all share the following characteristics: rapid efficacy (seconds to minutes), relatively short duration of action, sedative effect, and the potential for hypotension and respiratory depression. Lorazepam has emerged as the drug of choice for the initial management of epilepsy, because it terminates seizure rapidly (within 2 minutes) and has a shorter duration of action (4 to 6 hours, compared with 20 minutes for diazepam), thus necessitating fewer repeat doses. For this reason, it is also the preferred agent for control of alcohol withdrawal seizures. Lorazepam is available intramuscularly and as a sublingual preparation for out-of-hospital control of seizures in children. An advantage of diazepam is that it is in liquid form at room temperature and is therefore available premixed in resuscitation kits, and it can be administered quickly and without a need for reconstitution by the intravenous, endotracheal, or intraosseous route. It also is available in a rectal gel formulation. Its onset of action with intravenous administration is within 10 to 20 seconds, but a 50% chance of recurrent seizure within 2 hours if diazepam is used alone has been noted. Midazolam’s onset of action is within 1 minute; it is available in both intranasal and buccal formulations, and among the benzodiazepines it has the least cardiovascular effect.

Second-line abortive anticonvulsant therapy consists of phenytoin (Dilantin) and phenobarbital. Phenytoin reduces the repetitive firing of action potentials through sodium channel blockade, thereby stabilizing neuronal membranes.

Phenytoin neither sedates patients nor causes respiratory depression, but rapid intravenous administration of phenytoin in its propylene glycol diluent may cause hypotension and cardiac bradydysrhythmias, as well as local vascular injury, including venous thrombosis and localized tissue necrosis (purple glove syndrome). It should therefore be administered through a 20 gauge or larger line proximal to the forearm, at a rate no faster than 50 mg/minute, and the patient should have a cardiac monitor. Phenytoin’s onset of action is within 10 to 30 minutes, and intravenous administration typically requires at least 20 minutes. The duration of action is approximately 24 hours. Continued benzodiazepine dosing is appropriate until phenytoin achieves adequate brain levels.

Fosphenytoin is a water-soluble prodrug form of phenytoin, with a more physiologic pH. Its main advantages are that it is not likely to precipitate during intravenous infusion and that it also can be administered intramuscularly, although the volume required for full loading by the intramuscular route may be in the range of 20 mL or more. Although fosphenytoin can be infused more rapidly, the time to therapeutic concentration of the active drug is the same as for intravenous phenytoin. The hemodynamic advantages of fosphenytoin over intravenous phenytoin have not proved to be significant. Its use is most appropriate when intravenous access is not obtainable or when the intravenous line is of small gauge, as is often the case in children or the elderly. If levels of phenytoin or phenobarbital are subtherapeutic in a patient already being treated for seizures, loading doses can be given intravenously; alternatively, an adjusted oral dosing schedule can be prescribed to boost the serum level over 24 to 48 hours. Oral loading of phenytoin is associated with fewer adverse events than those noted with loading with either intravenous phenytoin or fosphenytoin, but its use may be limited when therapeutic activity is required urgently.

Phenobarbital is similar to benzodiazepines in that it binds to and enhances the inhibitory neurotransmitter GABA, thereby acting as a CNS depressant that decreases ictal and physiologic cortical electrical activity. Sedation and depression of respiratory drive and blood pressure must be anticipated, and, for this reason, non-sedating phenytoin is preferred. The onset of action of phenobarbital is within 15 to 30 minutes, and the duration of action is 48 hours.

Valproic acid administered intravenously has recently been recognized as a safe and effective treatment for seizures, especially in patients with allergies to phenytoin, the elderly, and patients with cardiorespiratory instability who might be at increased risk of adverse events from phenytoin. Valproic acid administered intravenously has been shown to be as effective as phenytoin given intravenously in patients with benzodiazepine-refractory status epilepticus, with fewer cardiopulmonary side effects. Hyperammonemic encephalopathy after valproic acid loading has been reported and should be evaluated by determination of serum ammonia level in a patient who does not regain consciousness after seizure resolution. Appropriate ED dosing regimens for the
benzodiazepines, phenytoin, fosphenytoin, phenobarbital, and valproic acid are listed in Table 100-1. Although such agents are being given to abort ongoing seizure activity, ED management must include a search for other underlying reversible causes. This search may prompt administration of dextrose for hypoglycemia, pyridoxine (vitamin B₆) for isoniazid overdose, sodium for hyponatremia, or magnesium for eclampsia.

Eclampsia complicates 1 in 1000 deliveries in the United States⁹⁰ and can occur ante partum (91% of cases occur after 28 weeks of gestation), in the peripartal period, or up to 4 weeks post partum.¹⁰⁹,¹¹⁰ Abortive treatment for eclamptic seizures is with magnesium sulfate, which is superior to either diazepam or phenytoin in limiting maternal mortality and preventing further seizures in eclampsia.¹¹¹,¹¹² The loading dose of magnesium sulfate is 4 to 6 g, followed by an infusion of 2 g/hour for 24 hours.¹¹³,¹¹⁴,¹¹⁵ Because hypermagnesemia may cause respiratory arrest, it is essential to monitor patients for hyporeflexia, which precedes respiratory compromise. In the uncommon event of excessive neuromuscular blockade secondary to respiratory compromise caused by magnesium sulfate, 1 g of 10% calcium gluconate is an effective reversal agent.¹¹⁶ Simultaneous reduction in blood pressure in the eclamptic patient, using hydralazine, labetalol, or nicardipine, is recommended.¹⁶

Nonpregnant patients who continue having seizures in the ED despite management with benzodiazepines, phenytoin, or phenobarbital are likely to meet the clinical criteria for refractory status epilepticus. Additional therapeutic measures include use of valproate, midazolam infusion, propofol infusion, barbiturate coma, and general inhalational anesthesia. Valproate, which increases GABA concentration, may be given intravenously in status epilepticus (see Table 100-1).¹² Another alternative is the use of propofol, a nonbarbiturate anesthetic agent with hypnotic and anticonvulsant activity. Studies suggest that propofol acts at a location other than the benzodiazepine-binding site and modifies the chloride channel by a mechanism that is different from, and possibly synergistic with, those for benzodiazepines and barbiturates. Propofol usually is administered as an intravenous loading dose of 1 to 3 mg/kg; this is followed by an infusion of 1 to 15 mg/kg per hour,¹¹⁷ with continuous EEG monitoring to ensure persistent burst suppression.¹¹⁸

Barbiturate coma is effective in terminating seizures by facilitating GABA, although it also suppresses all brainstem function. Neurologic consultation is advisable beforehand, however, because barbiturate coma may induce respiratory arrest, myocardial depression, and hypotension while decreasing intracranial pressure and increasing cerebral perfusion. The preferred agent for barbiturate coma is pentobarbital (see Table 100-1). Patients require intubation and ventilatory support, continuous cardiac monitoring, and invasive hemodynamic monitoring. Pressors may be required to support the blood pressure.¹¹⁹

Isoflurane anesthesia is one final alternative in the management of refractory ictus. Halothane is associated with more hemodynamic and hepatotoxic complications. Isoflurane suppresses electrical seizure foci and is easily titratable. Patients managed with barbiturate coma or inhalational anesthesia require intubation and mechanical ventilation. Intubation of a patient with ongoing seizure activity is best facilitated by using a benzodiazepine as an induction agent and lidocaine (1 mg/kg) as a pretreatment medication. Lidocaine reduces the increase in intracranial pressure that reflexively results from laryngoscopy and intubation.

The visible manifestations of convulsive ictus are extinguished by neuromuscular blockade. When a seizing patient is paralyzed and intubated, it cannot be assumed that pharmacologic therapy has terminated the seizure. Anticonvulsants should be administered, and EEG monitoring of the patient should be arranged. Without EEG, detection of seizure activity in a heavily sedated or paralyzed patient is difficult.

### Long-Term Management

Identifying a new-onset seizure disorder in the ED should prompt consideration of the need for further management in the following three areas: pharmacologic, psychosocial, and legal. The primary dilemma concerns whether to initiate prophylactic anticonvulsant therapy after one seizure. The deci-

EEG, electroencephalogram; PE, phenytoin equivalent.

sion to treat should be based on (1) ensuring that the diagnosis of seizure is correct, (2) ascertaining the likelihood of seizure recurrence, (3) assessing the benefit versus risk of anticonvulsant therapy, and (4) discussing with the patient their approach to risk. Even when witnessed in the ED, apparent ictal activity may not be a seizure. Diagnosing a seizure is more difficult when the event resolved before the patient’s arrival at the ED and is based on witness reports. In patients diagnosed with a seizure, 20 to 25% are subsequently found to have been misdiagnosed.

The risk of seizure recurrence is difficult to estimate in the ED setting. In patients with an initial unprovoked seizure, the 2-year risk of recurrence without treatment generally is considered to be less than 50%.

The presence of EEG abnormalities suggests greater risk, but this information usually is unavailable in the ED setting. Other factors associated with an increased risk of recurrence are partial (versus generalized) ictus, status epilepticus, a history of intracranial surgery or trauma, and the presence of a persistent neurologic abnormality, such as Todd’s paralysis.

The presence of specific underlying conditions may affect the decision to institute long-term therapy. For example, it would be reasonable to initiate antiepileptic therapy for an initial seizure in an HIV-positive patient when the seizure is thought not to be due to correctable factors such as drug toxicity or metabolic derangement. Alcohol-related seizures are notoriously unresponsive to anticonvulsants. Prophylaxis against post-traumatic seizures beyond the first week after injury probably is unnecessary, but the occurrence of early post-traumatic seizures should prompt at least short-term initiation of therapy. Furthermore, if a patient not receiving antiepileptic therapy presents to the ED with a second seizure, then initiating treatment is warranted because of the estimated 70% risk of recurrent events.

The side effects of anticonvulsants can be debilitating for the patient (Table 100-2). These effects must be considered before such therapy is initiated, particularly in women of reproductive age, because some anticonvulsants are teratogenic and furthermore may precipitate failure of oral contraceptives.

In the absence of specific underlying conditions that increase risk of recurrence, most authorities do not recommend initiation of anticonvulsant therapy from the ED after a single unprovoked seizure in adults. If the seizure was provoked, the decision should be based on whether the provoking factor can be corrected; if it cannot, anticonvulsant therapy should be initiated. The anticonvulsant dosing regimen for a patient with known epilepsy should be modified only in consultation with the patient’s physician (Table 100-3).

Drug monotherapy is always preferable in anticonvulsant regimens. The choice of drug to initiate antiepileptic therapy

PE, phenytoin equivalents.

is complex and depends on numerous factors, including the type of seizure, any comorbid conditions, other medications the patient is taking, and the potential for pregnancy, and is best determined in consultation with a neurologist, ideally after MRI neuroimaging and an EEG. However, if an antiepileptic drug is to be initiated in the ED, then the choice is among the three medications with the strongest evidence for efficacy in the treatment of a tonic-clonic seizure of either generalized-onset or partial onset with secondary generalization: carbamazepine, phenytoin, and valproate. It is essential to inform women of childbearing age that carbamazepine and phenytoin decrease the efficacy of oral contraceptive pills, so a second form of contraception should be used until consultation with a neurologist. Valproate, although not altering the efficacy of oral contraceptives, carries a high risk of teratogenic effects and is therefore not an ideal first-line agent for women of childbearing years.

The psychological and social implications of the new diagnosis of a seizure disorder should not be underestimated. Fear of seizures and stigmatization are common; employability and insurability may be adversely affected. Although the emergency physician is not usually in a suitable position to arrange for counseling, referral to local epilepsy support groups may be helpful.

The diagnosis of a new-onset seizure disorder has legal implications as well. Each state has regulations regarding driving privileges in patients with seizures, and some states require reporting by the physician. Accordingly, ED management should ensure compliance with such regulations, including informing patients about any restrictions. Patients also should be advised to refrain from hazardous or isolated activities until cleared to do so by their primary care physician. The need for a “medical alert” bracelet or other medical condition identifier should be stressed.

Finally, patients and their families should be counseled about seizure first aid, safety precautions such as avoiding swimming alone or operating dangerous machinery, and triggers for recurrence such as photic stimuli, sleep deprivation, and alcohol.

The references for this chapter can be found online by accessing the accompanying Expert Consult website.
Headache is a common complaint, more frequent than the common cold, and accounts for approximately 3 million visits to the emergency department (ED) per year in the United States. In addition, many more patients present with headache as part of a constitutional illness, making the symptom of headache one of the most frequent complaints in the ED.

Headache commonly is divided into primary and secondary disorders. The primary headache disorders include migraine, cluster, and tension-type headaches, which represent greater than 90% of headaches seen in clinical practice. Secondary headache disorders include a variety of organic illnesses in which head pain is a symptom of an identifiable, distinct pathologic process. To facilitate a standardized approach to headache management, the International Headache Society (IHS) published classification and diagnostic criteria for “headache disorders, cranial neuralgias, and facial pain” in 2004. This comprehensive and widely accepted system includes 14 categories of headache disorders and uses specific operational diagnostic criteria to define each headache type (Box 101-1). This revised classification system offers better separation of primary and secondary headaches and more standardized criteria for diagnosing secondary headaches.

The vast majority of patients presenting with headache have a benign primary headache disorder requiring only symptomatic treatment and referral. The challenge for the emergency physician is to identify the very small subset of patients who have headache as a symptom of a serious or potentially life-threatening disease (see Chapter 16).

### PRIMARY HEADACHE DISORDERS

#### Migraine Headache

**Principles of Disease.** Migraine is a common, chronic, sometimes incapacitating neurovascular disorder, characterized by attacks of severe headache, autonomic nervous system dysfunction, and, in some patients, an aura involving neurologic symptoms. It is a primary headache disorder believed to have a genetic basis.

Migraine headaches account for approximately 1 million visits to the ED per year. They typically begin in the second decade of life, peaking in early to midadolescence, and are more prevalent among women (17%) than among men (6%). During childhood, however, there is no gender difference in the prevalence of migraine. After menarche a correlation between migraine headache and menses is found in approximately 15% of female migraine sufferers, possibly related to fluctuating estrogen and progesterone levels. After menopause, women also tend to experience fewer migraine headaches. The lifetime prevalence of migraine is at least 18%. As many as 60% of women with migraines report an association between migraine and menstruation.

Historically, migraine headaches have been considered to be vascular in origin. According to this hypothesis, an initial phase of cerebral vasoconstriction resulting in neurologic symptoms (migraine with aura) is followed by a vasodilatory phase, manifested by the typical pounding headache of migraine. Appropriate changes in blood flow have been demonstrated for the classic migraine attack, and pain relief provided by vasoconstriction has been cited as further support for this hypothesis. However, this mechanism does not fully explain the entire spectrum of migraine attacks, and migraine is no longer thought to be caused by a primary vascular event. It is now believed that the pathophysiologic cause of migraine may actually originate in the brainstem within its descending and ascending circuitry, including the ascending pain-modulating projections from the midbrain raphe nuclei. Evidence suggests a perturbation of neural activity within this serotonergic system as an important precursor to migraine.

Changes in serotonergic activity can alter the cranial circulation, triggering a “vascular phase.” In addition to constriction and dilatation of intracranial and extracranial arteries, this neurovascular reaction activates the nociceptive trigeminal vascular system. Neural connections between cerebral blood vessels and the trigeminal nerve release neuropeptides that can induce a painful neurogenic or sterile inflammation.

Agonists of the 5-hydroxytryptamine (5-HT) 1B/1D receptor, such as sumatriptan or dihydroergotamine, block the inflammatory process. Effective prophylactic agents are believed to act as antagonists of the 5-HT1 receptor site.

Migraine is further divided into two major categories. Migraine without aura, or “common migraine,” is the most frequent form of migraine and accounts for approximately 80% of all cases (Box 101-2). “Classic migraine,” or migraine with aura, has specific reversible neurologic symptoms that precede the actual headache (Box 101-3) and is seen less frequently.

**Clinical Features.** Migraine headaches tend to be chronic and recurrent. The headache often is unilateral, pulsating in quality, moderate to severe in intensity, and exacerbated by routine activities. The side of the headache can vary with individual attacks, and the headache may be bilateral in 40% of patients. The onset usually is gradual, and the attacks typi-

MIGRAINE WITH AURA (CLASSIC MIGRAINE): INTERNATIONAL HEADACHE SOCIETY CRITERIA

A. At least two attacks that fulfill criterion B
B. Presence of at least three of the following four characteristics for a diagnosis of classic migraine:
   1. One or more fully reversible aura symptoms indicating focal cerebral cortical or brainstem dysfunction (or both)
   2. At least one aura symptom developing gradually over more than 4 minutes, or two or more symptoms occurring in succession
   3. No single aura symptom lasting longer than 60 minutes
   4. Headache beginning during aura or afterward, with a symptom-free interval of less than 60 minutes (also may begin before aura)
C. Exclusion of related organic diseases by means of an appropriate history, physical examination, and neurologic examination with appropriate diagnostic tests

Available at http://ihs-classification.org/en/.

Many factors can trigger migraine headaches in predisposed persons. Common precipitants include sleep deprivation, stress, hunger, hormonal changes including menstruation, and the use of certain drugs including oral contraceptives and nitroglycerin.8 In addition, some patients report specific food sensitivities including chocolate, caffeine, and foods rich in tyramine, monosodium glutamate, and nitrates.22,23 Alcohol, specifically red or port wine, has also been implicated. In others, certain sensory stimuli such as a strong glare or strong odors, loud noises, or weather changes can trigger an attack.24

Differential Diagnosis. Because of the complexity of the symptomatology, migraine headaches may be difficult to distinguish from other, secondary causes of headache. Other disorders that mimic migraine include ruptured berry aneurysm, arteriove-

For mild to moderate attacks, the IHS recommends simple analgesics such as acetaminophen or nonsteroidal anti-inflammatory drugs (NSAIDs). In the presence of nausea or vomiting, adding an agent such as metoclopramide enhances the absorption and effectiveness of these medications. Appropriate doses and possible side effects are listed in Table 101-1.

For moderate to severe attacks, several classes of medications are available to treat the pain in addition to the nausea and vomiting that frequently accompany the headache. Specific agents available for treating severe migraine include DHE and the triptans. DHE should be given intravenously (IV) in a dose of 1.0 mg over 2 minutes; this can be repeated in 1 hour if pain control has not been achieved. Because DHE can cause nausea and vomiting, patients should be pretreated with an antiemetic such as metoclopramide 10 mg IV or prochlorperazine 5 mg IV. Repeated administration of the intravenous form of DHE has been shown to be very effective in patients with intractable migraine and status migranosus (i.e., a migraine attack lasting more than 72 hours). Contraindications to using DHE include pregnancy, breast-feeding, poorly controlled hypertension, coronary artery disease, and peripheral vascular disease. DHE should not be used if the patient has already taken any drug in the triptan class.

Sumatriptan, the first-approved medication of the triptan class, is a selective 5-HT (1B/1D) receptor agonist. Other triptans that are available include zolmitriptan, naratriptan, and rizatriptan, but only sumatriptan is available for subcutaneous administration, and it is the most common preparation used in the ED setting. The initial dose is 6 mg given subcutaneously, which may be repeated once in 1 hour if the patient has a partial response to the first dose. Common side effects include tingling, flushing, warm or hot sensations, and heaviness in the

</table>
chest. Sumatriptan has contraindications similar to those for DHE and should not be used within 24 hours of administration of an ergotamine-containing medication or DHE. In addition to the subcutaneous preparation, sumatriptan and the other triptan agents are available in oral formulation for the treatment of acute migraine attacks.

Neuroleptics also have been shown to be effective in treating acute migraine attacks. Prochlorperazine can be administered as a slow 10-mg intravenous bolus, which can be repeated once in 30 to 60 minutes. The most common side effects after parenteral administration include sedation, postural hypotension, and extrapyramidal symptoms including acute dystonic reactions.

Narcotic analgesics such as morphine should be reserved for patients who do not respond or have contraindications to standard migraine therapies. Although frequently used, narcotics have been shown to be less efficacious than other agents and are associated with a risk of addiction; however, some patients obtain relief with this class of medications.

The use of steroids for the treatment of migraine remains controversial. Anecdotal evidence suggests that they may be effective for prolonged migraine attacks that are refractory to standard therapies and for treating status migrainosus.

Occasionally, patients do not respond to initial therapy in the ED and require hospitalization for continued pain control and supportive therapy.

**Prophylactic Therapy.** Prophylactic therapy is indicated for patients who have frequent attacks (more than two or three episodes per month), prolonged attacks lasting more than 48 hours, or attacks that are severe and debilitating. Of note, prophylactic medications are seldom more than 55 to 65% effective.

Several classes of medications are used for the prophylaxis of migraine. Many of these medications have significant side effects, especially among women of childbearing age; therefore, after headaches have decreased, attempts should be made to taper and discontinue treatment when possible.

Beta-adrenergic blocking agents reduce both the frequency and severity of migraine headache and are the drugs most widely used for prophylaxis in patients with recurrent migraine. Propranolol has been the most extensively studied medication. Patients who do not respond to propranolol may respond to another drug in this class, which includes atenolol, metoprolol, timolol, and nadolol. Contraindications to beta-blockers include pregnancy, asthma, heart failure, Raynaud’s phenomenon, and diabetes mellitus.

Other medications used for migraine prophylaxis include calcium channel blockers, tricyclic antidepressants, anticonvulsants including divalproex sodium and sodium valproate, and monoamine oxidase inhibitors.

Methysergide, a semisynthetic ergot preparation, also has been widely used for prophylaxis. It is a potent peripheral serotonin antagonist with a presumed mechanism of action similar to that for other ergot drugs. Its use is contraindicated in patients with coronary artery or peripheral vascular disease. Prolonged use has been associated with retroperitoneal, pulmonary, and endocardial fibrosis.

**Cluster Headache**

**Perspective.** Cluster headache is the only headache syndrome that is more common in men than in women. It typically occurs in young to middle-aged adults who smoke, with a peak incidence in the late 20s. The headaches tend to occur repeatedly over a defined time interval—hence the term “cluster.” Several attacks can occur in 1 day, and a typical cluster period may last 6 to 8 weeks. Several precipitating factors have been implicated, most notably the ingestion of alcohol. Stress and climatic changes may also play a role in susceptible persons.

**Clinical Features.** Cluster headaches occur suddenly with little warning, and several episodes can occur within a 24-hour period. Each headache lasts from a few minutes up to 2 hours. The headache typically begins with a unilateral sharp, stabbing pain in the eye, which may awaken the patient from sleep. The attacks tend to occur exclusively in the territory of the trigeminal nerve. Unlike the migraineur, the patient with cluster headache presents in a predictable fashion (i.e., holding a hand to the affected eye, rocking, rubbing the head, and pacing). The attack subsides rapidly, often leaving the patient exhausted.

Up to 30% of patients have a partial Horner’s syndrome with ptosis and miosis. The eye often is injected and tearing, and many patients have unilateral nasal congestion.

**Differential Diagnosis.** Other headache disorders that mimic cluster headache include migraine, trigeminal neuralgia, and chronic paroxysmal hemicrania (CPH). With migraine, the clinical presentation, gender, and age distribution usually are different. With trigeminal neuralgia, the pain peaks within seconds, lasts only a couple of minutes, and can be provoked by specific trigger points on the face or oral mucosa. CPH is manifested by a brief unilateral headache that recurs at least 15 times a day, often induced by rotation or turning of the head or by pressure on the cervical spine.

**Treatment.** Because cluster headaches are abrupt in onset, treatment must be initiated rapidly to be effective. At present, subcutaneous sumatriptan 6 mg is the preferred abortive therapy in most cases if it can be given very early after the onset of the attack; however, by the time the patient presents to the ED, a full-blown headache usually has developed, and symptomatic treatment is indicated. High-flow oxygen at a rate of 7 to 10 L/minute has been shown to abort the headache within several minutes. DHE 1 mg given IV or intramuscularly (IM) also has been shown to be effective, but it is less practical than oxygen administration and has more side effects.

For patients who do not respond to these measures, intranasal application of cocaine or lidocaine to produce anesthesia of the sphenopalatine region has been advocated by some clinicians but has not gained widespread acceptance.

In addition to acute therapies, several medications have been shown to be effective for the prophylactic treatment of cluster headaches. A short course of oral prednisone may effectively abort a cluster attack in some patients. A recommended regimen is 60 mg of prednisone daily for 10 days, followed by a 1-week taper. To prevent breakthrough headaches after the steroid taper, patients may require the concurrent administration of another prophylactic agent (e.g., verapamil, lithium carbonate, methysergide).

**Tension Headache**

**Perspective.** Tension headache is the most common recurrent pain syndrome, affecting more than 78% of the population. Women are affected more frequently (80% in all women) than men (66%), and most patients are middle-aged. The headaches typically do not cause significant disability, and patients are able to continue with their normal daily activities. The median frequency of headaches is six per month, and stress and lack of sleep are implicated as triggering factors. The average duration of the headache is 4 to 13 hours, with a maximum of 72 hours.

Little is known about the pathophysiology of tension headache. There is no clear evidence that increased muscle activity is present, and the physical examination will reveal tender areas of the scalp and neck with both tension and
Subarachnoid Hemorrhage

Principles of Disease. Subarachnoid hemorrhage (SAH) refers to extravasated blood in the subarachnoid space. Presence of the blood activates meningeal nociceptors, leading to diffuse occipital pain along with signs of meningismus. SAH accounts for up to 10% of all strokes and is the most common cause of sudden death from a stroke.

Approximately 80% of patients with nontraumatic SAH have ruptured saccular aneurysms. Other causes include arteriovenous malformations, cavernous angiomas, mycotic aneurysms, neoplasms, and blood dyscrasias. SAH may be caused secondarily by an intraparenchymal hematoma that disrupts its way into the subarachnoid space.

The risk for aneurysmal SAH increases with age, with most cases occurring between the ages of 40 and 60 years. In children and adolescents, aneurysms are uncommon, and when SAH occurs it usually is secondary to an arteriovenous malformation. It is estimated that 5% of the general population harbor a berry aneurysm, and the risk of rupture may increase with aneurysmal size. Other risk factors associated with SAH include hypertension, smoking, excessive alcohol consumption, and sympathomimetic drugs. Increased systolic blood pressure values and long-term hypertension before aneurysm rupture seem to predict fatal SAH independently of aneurysm size or the patient’s age at the time of rupture; patient gender also does not influence mortality. A familial association of cerebral aneurysms with several diseases, including autosomal dominant polycystic kidney disease, coarctation of the aorta, Marfan’s syndrome, and Ehlers-Danlos syndrome type IV, has been described.

Of all patients presenting to the ED with headache, 1 to 4% have SAH. Many patients with SAH die before reaching the hospital, with preadmission mortality rates ranging from 3% to 26%. Because of the significant morbidity and mortality associated with this condition (with reported rates of up to 50%) and the high likelihood of clinical deterioration in patients who initially are misdiagnosed, SAH should be a primary consideration in the initial ED evaluation. Accordingly, familiarity with its presentation is essential.

Clinical Features. A majority of patients with SAH present with a sudden, cataclysmic “thunderclap” headache, which often is described as “the worst headache of [their] life.” The onset of headache may be associated with exertional activities such as exercise, the Valsalva maneuver, or sexual intercourse in up to 20% of patients. One study demonstrated that moderate to extreme physical exertion in the previous 2-hour period was associated with a tripling of the risk for SAH. Associated signs and symptoms include nausea and vomiting in approximately 75% of patients, neck stiffness in 25%, and seizures in 17%. Some patients experience a headache within the previous 6 to 8 weeks, indicating a warning leak or sentinel hemorrhage. Physical findings depend on the extent of the SAH. Meningismus is present in more than 50% of patients, and up to 20% have focal abnormalities. Funduscopic examination may reveal retinal or subhyaloid hemorrhages, and patients also may have an isolated third or sixth nerve palsy. Oculomotor (third) nerve compression secondary to an expanding aneurysm leads to pupillary dilation. Approximately 50% of patients with a ruptured aneurysm are restless or have an altered level of consciousness. Although a majority do not have focal neurologic signs, such signs when present may indicate the site of the aneurysm.

The patient’s prognosis is related to neurologic status at hospital admission. The Hunt and Hess scale stratifies patients according to their clinical signs and symptoms at the time of presentation and is predictive of outcome. Patients who present with a grade I or II hemorrhage tend to have a good prognosis, and patients in grades IV and V tend to do poorly. These latter patients have an altered mental status, ranging from stupor to deep coma, together with focal neurologic signs and symptoms. Patients with grade III hemorrhage present with drowsiness or confusion and are at risk for rapid clinical deterioration.

Diagnostic Studies. When the diagnosis of SAH is considered, a CT scan should be ordered emergently. Figure 101-1 shows an example of SAH on a CT scan. For acute hemorrhage less

Blood pressure management should be determined by the patient’s clinical status with involvement of the treating neurosurgeon. A typical goal would be a systolic blood pressure less than 160 mm Hg or a mean arterial pressure less than 130 mm Hg unless vasospasm is present.

Analgesics, including opioids, should be used for persistent headache. In patients who are nauseated or at risk for vomiting, antiemetics also must be administered. Agitated patients require sedation, and all patients should be placed at bedrest in a quiet and dark environment. Clinically evident seizures should be treated with anticonvulsants, but the prophylactic use of these drugs is controversial. A majority of these patients require hemodynamic and ICP monitoring in an intensive care setting. The role of surgery (e.g., aneurysmal clipping) versus endovascular coil embolization is not yet fully defined.

Brain Tumor

Principles of Disease. Headache is the most common presenting complaint with brain tumor, being reported by approximately 50% of the patients. A majority of these patients are elderly and have a cerebral metastasis as a cause of their headache. The most common causes of metastasis are lung and breast carcinoma, followed by malignant melanoma and carcinomas of the kidney and gastrointestinal tract. Primary brain tumors are much less common and typically occur in adults younger than 50 years.

The headache can be caused by several mechanisms, including direct involvement and traction on pain-sensitive structures such as meninges or larger cerebral vessels, or may be a symptom of increased ICP. The pain patterns produced are highly variable, depending on the location of the mass and the structures involved. Headaches often but not always are on the same side as the tumor. With increased ICP, the pain often is bifrontal or bioccipital and may be accompanied by vomiting. Brain tumors also may disrupt sleep, awakening the patient during the night. This effect may be related to increases in cerebral pressure that occur with recumbency and sleep-related carbon dioxide retention. Rapidly growing tumors are more likely to be associated with headache.

Clinical Presentation. The typical patient presents with complaints of a worsening headache that has been present for weeks to months. The headache may have been present initially only on awakening, gradually becoming continuous. The classic triad of brain tumor headache—sleep disturbances,
severe pain, and nausea and vomiting—is seen in only one third of patients.68 Vomiting, when present, may be projectile and not preceded by nausea. If increased ICP is present, the headache often is bilateral and worsened by coughing, sneezing, bending, defecation, and sexual intercourse.69 Although patients may not complain of focal neurologic deficits, abnormal findings are often found with neurologic testing.70 Other presentations include seizures, personality changes, and cognitive difficulties.

**Diagnostic Evaluation.** The diagnosis of brain tumor is often suspected from the history and neurologic examination. Neuroimaging with CT or magnetic resonance imaging (MRI) is the most efficient way to confirm the diagnosis. Contrast enhancement on CT often improves the identification of the underlying mass lesion and helps differentiate it from other causes, including abscess, hematoma, and vascular malformation.70

**Treatment.** Management consists of urgent referral to neurosurgery and treatment of any acute complications, including increased ICP and seizures. For patients who present with symptoms suggestive of increased ICP (e.g., headache, nausea, vomiting, confusion, weakness), treatment with steroids has been shown to be beneficial. Dexamethasone is the high-potency steroid used most often to treat edema associated with brain tumors. It has several advantages over other glucocorticoids, including a longer half-life, reduced mineralocorticoid effect, and a lower associated incidence of cognitive and behavioral complications.70 The exact dose of steroids necessary for each patient varies in accordance with histology, size, and location of the tumor and the amount of edema present. In general, most patients require between 8 and 16 mg of dexamethasone per day. An appropriate starting dose in the ED is 10 mg IV, followed by 4 mg every 6 hours.

Patients with a seizure (generalized or partial) should receive anticonvulsant therapy. Appropriate first-line agents include phenytoin, carbamazepine, and valproic acid. Empirical or prophylactic treatment does not appear to delay or prevent the onset of seizure activity and may expose the patient to unnecessary complications and toxicity.70

**Giant Cell Arteritis**

**Principles of Disease.** Giant cell arteritis, or temporal arteritis, is a systemic inflammatory process of the small and medium-sized arteries. Extradural branches of the aortic arch and the ophthalmic vessels most commonly are involved, but the process may affect any artery in the body.71 The mean age at onset is 71 years, and it is rare before age 50. Females are affected more commonly than males.

**Clinical Presentation.** Headache is the most common initial manifestation of giant cell arteritis and occurs in more than 70% of patients with this disorder.72 The headache often is of 2 to 3 months’ duration and can be continuous or intermittent and often worsens at night or on exposure to cold. The pain may be described as sharp, throbbing, boring, or aching and usually is localized to the temporal region but may occur anywhere in the head. The physical examination may reveal tenderness over the scalp in the area of the temporal artery, with exacerbation of the pain by wearing a hat or resting the head on a pillow. Patients also may experience jaw claudication secondary to vascular insufficiency of the masseter and temporalis muscles. Systemic signs and symptoms including fever, anorexia, and weight loss often are present. Approximately 40% of patients complain of pain in their large proximal joints, with symptoms referable to the neck, torso, and lower back. Typically, pain and stiffness are worse in the morning and lessen as the day goes on.72 This condition, known as polymyalgia rheumatica, can occur in the absence of giant cell arteritis.

The most serious complication of giant cell arteritis is permanent visual loss, which eventually occurs in 36% of untreated cases.73 Amaurosis fugax also can occur before permanent visual loss. Other complications include peripheral neuropathies, transient ischemic attacks, and stroke.

**Diagnostic Evaluation.** The physical examination may reveal abnormalities of the temporal arteries, including tenderness, reduced or absent pulsations, erythema, and nodularity or swelling, best detected by light palpation just anterior and slightly superior to the tragus of the ear.74 Visual acuity and visual field testing and a thorough fundoscopic examination also should be performed.

A majority of patients have a significant elevation of the erythrocyte sedimentation rate (ESR), usually to more than 50 mm/hour and often more than 100 mm/hour, although an elevated ESR is not specific for the disorder and a normal value does not rule out the diagnosis. Other abnormalities on laboratory studies include mild to moderate anemia, elevated C-reactive protein level, and liver function abnormalities.75 An elevated platelet count (greater than 400,000/µL) may be a risk factor for permanent visual loss.75 The diagnosis is confirmed by temporal artery biopsy. Because this is a patchy disease, multiple biopsy specimens of a long segment of the artery may need to be examined.

**Treatment.** Because of the risk of visual loss, giant cell arteritis constitutes a medical emergency, and treatment should be initiated promptly when the diagnosis is suspected. Steroids are the mainstay of therapy; the recommended initial dose of prednisone ranges from 60 to 120 mg/day. Symptomatic response usually occurs rapidly over days, although therapy must be continued for months, with close ESR monitoring.

**Carotid and Vertebral Dissection**

**Principles of Disease.** Carotid and vertebral dissections are more common than previously realized. They are the most frequent cause of stroke in persons younger than 45 years, accounting for approximately 20% of all cases in this age group.76 Although dissections may occur spontaneously, careful history taking frequently identifies an association with sudden neck movement or trauma preceding the event.76,77 Reported mechanisms include neck torsion, chiropractic manipulation, coughing, minor falls, and motor vehicle accidents. Early symptoms and signs are often subtle, and in the absence of neurologic findings delays in diagnosis are common. The median delay from symptom onset to diagnosis was seven days in one report.77

The pathologic lesion is intramural hemorrhage within the media of the arterial wall. The hematoma can be localized or extend circumferentially along the length of the vessel, resulting in partial or complete occlusion. Platelet aggregation and thrombus formation also occur, further compromising vessel patency or causing distal embolization. The timing of these events is variable, and a patient may experience symptoms of cerebral ischemia days to years after dissection.78,79

**Clinical Presentation.** The typical presentation of the patient with carotid or vertebral dissection is the abrupt onset of pain in the neck or face. Neurologic findings usually occur within the first few hours, but autopsy studies have shown that strokes may occur months later.76

**Carotid Dissection.** The classic triad of symptoms for carotid dissection includes unilateral headache, ipsilateral Horner’s syndrome, and contralateral hemispheric findings that may include aphasia, neglect, visual disturbances, or hemiparesis. The headache is often severe and throbbing but may be subacute and similar to previous headaches. Acute severe retro-orbital pain in a previously healthy person with no history of cluster headaches is particularly suggestive of carotid dissection.72
Most patients eventually develop signs of cerebral ischemia. Warning symptoms include transient ischemic attacks, amaurosis fugax, episodic light-headedness, and syncope. Spontaneous dissection of the carotid artery has a favorable prognosis and recurrence is uncommon. Factors associated with a worse prognosis include old age, occlusive disease on angiography, or stroke as the initial presenting symptom.

Vertebral Dissection. Vertebral artery dissections are less common than carotid dissections. The classic presentation is that of a relatively young person with severe, unilateral posterior headache and neurologic findings. The majority of patients develop a rapidly progressive neurologic deficit with symptoms of brainstem and cerebellar ischemia. Common findings include vertigo, severe vomiting, ataxia, diplopia, hemiparesis, unilateral facial weakness, and tinnitus. Spontaneous vertebral artery dissection appears to be relatively rare. Approximately 10% of patients who develop a vertebral dissection die during the acute phase, secondary to massive stroke. For patients who survive, the prognosis is usually good.

Diagnosis and Treatment. The diagnosis of dissection may prove to be difficult. A CT scan should be obtained first but is often normal in uncomplicated dissection. Further imaging studies, including MRI, magnetic resonance angiography, or catheter angiography are required to confirm the diagnosis. Figure 101-2 shows an example of carotid artery dissection on MRI. Duplex imaging is of limited value. Treatment is aimed at stroke prevention and usually includes early anticoagulation followed by antplatelet therapy.

Identifying patients with dissection is challenging. More than 50% of patients see their physician for symptoms before admission. The emergency physician must consider the diagnosis in any young patient who presents with head or neck pain with focal neurologic findings.

Cerebral Venous Sinus Thrombosis

Principles of Disease. Thrombosis of the intracranial veins and sinuses is an uncommon cause of stroke, in contrast with arterial causes. Because of the significant associated morbidity, however, cerebral venous sinus thrombosis (CVST) is an important consideration in the differential diagnosis for headache in patients with suggestive signs and symptoms.

Numerous factors have been associated with the development of CVST, including genetic and hypercoagulable disorders, pregnancy and the puerperium, inflammatory systemic disorders including vasculitis and connective tissue disorders, head trauma, CNS infections, medications (e.g., oral contraceptives, steroids), and neurosurgical procedures (e.g., dural puncture, internal jugular vein infusions).

Clinical Presentation. The clinical presentation can be quite variable, depending on the location of the thrombosis. Common symptoms and signs include headache, nausea and vomiting, seizures, decreased level of consciousness that may progress to coma, and focal neurologic deficits. Papilledema is frequent with chronic cases but is less common with acute presentations. With cavernous sinus thrombosis, the clinical picture is dominated by ocular findings including orbital pain, proptosis, and paralysis of extraocular movements.

Diagnostic Evaluation. An elevated D-dimer level is present in approximately 90% of cases of CVST and, along with the clinical findings, can be used to determine the need for further diagnostic testing in individual patients. The diagnosis of CVST is based on neuroimaging of the area of thrombosis. CT by itself may reveal nonspecific lesions such as an infarct, hemorrhage, or edema. The key to diagnosis is to image the venous system itself, and this is best accomplished by a combination of MRI to visualize the thrombosed vessel and magnetic resonance venography (MRV) to detect nonvisualization of the same vessel. CT angiography/venography has also been used to visualize the cerebral venous system.

Treatment. Specific treatment of CVST includes anticoagulation to prevent propagation of the thrombosis as well as complications (e.g., pulmonary embolism). In patients whose clinical condition worsens despite anticoagulation, thrombolysis or thrombectomy may be considered in centers with expertise in interventional procedures. Seizures should be treated with anticonvulsants.

The prognosis with CVST is based on the underlying etiology and the development of complications. During the acute phase, the overall death and dependency rate is approximately 15%. Approximately two thirds of patients will recover without sequelae, however—a rate far superior to that among patients who suffer an arterial stroke.

Idiopathic Intracranial Hypertension

Principles of Disease. Idiopathic intracranial hypertension (IIH) also known as “pseudotumor cerebri” or “benign intracranial hypertension.” The term idiopathic intracranial hypertension, however, is preferred, because this disorder is not always benign and may have significant neurologic sequelae in affected persons.

IIH is a relatively common neurologic disease seen primarily in young obese women of childbearing age. Several predisposing factors have been identified, including the use of oral contraceptives, anabolic steroids, tetracyclines, and vitamin A.

Pathophysiology and Clinical Features. The pathophysiology of this disease remains controversial, with increased brain water content and decreased CSF outflow considered the two major causative factors. The most prominent symptom is generalized headache, which often is gradual in onset and of moderate intensity. No specific localizing pattern has been documented, although in some patients the headache is worsened by eye movement. It may awaken the patient from sleep and is exacerbated by bending forward and the Valsalva maneuver, both of which impede cerebral venous return.

Visual complaints are common, and patients may experience transient visual obscuration several times a day secondary to...
Post-traumatic Headache

Headache is the most common symptom after minor head injury. It often is part of a complex syndrome that can include dizziness, fatigue, insomnia, irritability, memory loss, and difficulty with concentration. The prevalence of headache with post-traumatic syndrome is not known, because most patients are not admitted for this condition. There are approximately 2 million closed head injuries per year, and post-traumatic headache (PTHA) occurs in an estimated 30 to 50% of patients with these injuries. Acute PTHA develops hours to days after the injury and resolves within 3 to 6 months. Chronic PTHA may last from several months to years and may mimic other forms of headache, including tension and migrainous headaches. The presence of headache, dizziness, or nausea on initial presentation is strongly associated with the development of chronic PTHA.

Patients in whom PTHA develops after minor head injuries have normal findings on neurologic examination and neuroimaging studies. The pathophysiologic mechanism for their symptoms is unclear and may have both anatomic and functional components. Most patients are more concerned about the cause of the headache rather than the headache itself.

Treatment is symptomatic. For acute PTHA, analgesics such as acetaminophen or NSAIDs are adequate for pain control. For chronic PTHA, treatment must be individualized depending on the type of headache and associated symptoms the patient is experiencing. Novel therapies, such as antidepressants and beta-blockers, may be effective in selected patients.

Acute Glaucma

Patients with acute angle closure glaucoma present with sudden onset of severe pain localized to the affected eye that may radiate to the ear, sinuses, teeth, or forehead. Visual symptoms, including blurriness, halos around lights, and sco- tomas, typically are present, and many patients also experience nausea and vomiting. The underlying pathophysiologic mechanism is congenital narrowing of the anterior chamber angle that, under certain conditions, closes, resulting in a significant rise in intraocular pressure (IOP). Episodes can be precipitated by entering a low-light environment such as a movie theater, with resultant pupillary dilation, or by the use of medications such as mydriatics (e.g., for dilated ocular examination), sympathomimetics (e.g., pseudoephedrine), or agents with anticholinergic properties (e.g., antihistamines, antipsychotics, antidepressants).

Physical examination reveals a red eye with a fixed, mid-dilated pupil, corneal clouding, and shallow anterior chamber. The diagnosis is confirmed by demonstrating markedly elevated IOP in the range of 60 to 90 mm Hg (normal is less than 21 mm Hg).

Treatment includes topical miotics, topical beta-blockers, oral carbonic anhydrase inhibitors (e.g., acetazolamide, 250 mg four times daily), intravenous osmotic agents (e.g., mannitol), and prompt referral to an ophthalmologist. The potential for diagnostic confusion between acute glaucoma, iritis, and cluster headache must be recognized. Although cluster headache may arise with pain, nausea, and a red eye, vision is not affected and the pupil generally is small and the eyelid is ptotic (from an oculosympathetic paresis). Acute iritis also arises with a painful red eye, but only acute angle closure glaucoma is associated with markedly elevated IOP.

Post-Dural Puncture Headache

Principles of Disease and Pathophysiology. Headache is the most common complication of lumbar puncture, occurring in up to 40% of patients. The incidence is highest in the 18- to 30-year age group, but this complication is uncommon in young children and in adults older than 60. Although the onset often is immediate, patients may not report symptoms for several days. In a majority of affected persons, the duration of headache is less than 5 days.

The cause of post–dural puncture headache (PDPH) is not entirely clear. The most likely explanation is a persistent CSF leak that exceeds CSF production, resulting in CSF hypotension. If sufficient CSF is lost, the brain descends in the cranial vault when the patient assumes the upright position, leading to increased traction on the pain fibers. Thus, the headache is characteristically positional and increases with the upright position and decreases with recumbency. The amount of time a patient remains recumbent after lumbar puncture does not appear to affect the incidence of headache.
Certain factors have been implicated as causes of PDPH, including the size or diameter of the spinal needle, the orientation of the bevel during the procedure, and the amount of fluid withdrawn. Smaller-diameter needles cause less leakage, and it is postulated that inserting the needle with the bevel up (i.e., bevel pointing up when the patient is in the lateral position) minimizes damage to the dural fibers. Using atraumatic needles or pencil-point needles (e.g., Whitaker or Sprotte) has also been shown to reduce significantly the incidence of PDPH.

Clinical Features. PDPH typically is bilateral, throbbing, and exacerbated by the upright position. Associated signs and symptoms include neck stiffness; nausea; vomiting; auditory disturbances, including tinnitus and hearing loss (hypoacusis); and ocular symptoms, including blurred vision and diplopia. It is postulated that inserting the needle with the bevel up (i.e., bevel pointing up when the patient is in the lateral position) minimizes damage to the dural fibers. Using atraumatic needles or pencil-point needles (e.g., Whitaker or Sprotte) has also been shown to reduce significantly the incidence of PDPH.

Treatment. Most PDPHs resolve spontaneously within a few days with bedrest, adequate hydration, and mild analgesics. For persistent headaches, methylxanthine agents have been found to help some patients. Oral caffeine (300 mg every 4 to 6 hours), caffeine sodium benzoate (500 mg in 1 L of fluid), or theophylline (300 mg PO every 8 hours) may be effective. For severe headaches lasting longer than 24 hours, an epidural blood patch (autologous blood clot) relieves the headache in the majority of patients.

Intracranial Infection

Headache is common among patients with intracranial infections, including meningitis, brain abscess, encephalitis, and acquired immunodeficiency syndrome. The severity and type of headache vary depending on the specific infection.

With acute bacterial meningitis, the patient often has a severe bursting headache that rapidly increases in severity over a short period. These patients typically have significant meningismus, with both Kernig’s and Brudzinski’s signs. With viral meningitis, patients also may complain of severe headache and nuchal rigidity, but the course is more indolent than with bacterial meningitis.

The severity of headache associated with encephalitis depends on the type of virus involved. For example, the headache is usually mild with mumps encephalitis. With herpes simplex infection, however, the headache is abrupt and severe and frequently is associated with confusion, fever, altered level of consciousness, seizures, and focal neurologic signs.

Patients with brain abscess often have headache as their presenting complaint. As the infection progresses, vomiting, focal neurologic signs, and depressed level of consciousness typically develop.

Headache is a frequent complaint in patients with human immunodeficiency virus infection and can be caused by a number of conditions, including aseptic meningitis, toxoplasmosis, cryptococcal or tuberculous meningitis, and cytomegalovirus encephalitis.

In a majority of cerebral infections, the mechanism of head pain includes meningeal irritation and increased ICP. In addition, headache may be a general reaction to fever or the toxic products of the infecting agent.

Hypertensive Headache

Contrary to common belief, hypertension is not an important cause of headache, and the occurrence of headache and hypertension in the same patient is often coincidental. Whether some patients with mild to moderate hypertension suffer from headache caused by elevated blood pressure is uncertain. The rate of blood pressure increase is more important as a cause of headache than the absolute blood pressure value. Diastolic pressures lower than 130 mm Hg are rarely the cause of headache.

Nonetheless, the association of headache with severe hypertension is well documented. Acute, severe headache is a prominent symptom of hypertensive encephalopathy, and most patients have blood pressure readings in the range of 250/150 mm Hg. Other conditions include headache secondary to toxic agents (e.g., drug-induced hypertension), pheochromocytoma, and eclampsia.

The headache of severe hypertension typically is diffuse and is worse when the patient awakes in the morning and gradually subsides over the course of the day. Treatment is directed at lowering the blood pressure; in most cases, the headache is relieved within 24 hours. In patients with hypertensive encephalopathy, the headache may persist for days until brain edema has resolved.

Cervicogenic Headache

Cervicogenic headache refers to headache originating from disorders of the neck. Diagnosis is based on the presence of one of the following three distinct sets of symptoms:

1. Unilateral headache triggered by movements of the head or neck or certain head positions
2. Unilateral headache triggered by pressure on the neck
3. Unilateral headache spreading to the neck or possibly the ipsilateral shoulder or arm

Many of these headaches are reported after a whiplash injury. Even though neck structures play a primary role in the pathophysiology of some headaches, clinical patterns indicating a neck-headache relationship have not been adequately defined.

Medication-Induced Headache

Medication use, abuse, or withdrawal can be a cause of headache, and the term medication-induced headache is used to describe these conditions. Medication-induced headache is underdiagnosed and often difficult to manage. Although not well understood, it tends to occur in patients with a primary headache disorder (e.g., migraine, tension-type) who use immediate-relief medications, often in excessive quantities. Medications that have been implicated include NSAIDs, aspirin or acetylsalicylic acid (ASA), acetaminophen, barbiturate-analgesic combinations plus caffeine with or without codeine, opioids, caffeine, and ergotamine. A key factor in medication overuse headache is preemptive use of drugs, in anticipation of—rather than for—headache. Women are affected more commonly than men, and the most frequently affected age group is that of persons between 30 and 40 years. The headache itself is variable and may be accompanied by asthenia, nausea, anxiety, depression, and difficulty with concentration. Typically, it is worse on awakening in the morning and after physical exertion.

The symptomatic medication that leads to the development of this disorder initially provides some pain relief to the patient, but over time tolerance develops, and larger doses are required to obtain symptomatic improvement. Treatment typically requires complete withdrawal of the medication being overused, to achieve long-term results. In addition, these patients require a comprehensive education and follow-up program with pharmacologic, dietary, and behavioral components.
Trigeminal Neuralgia

Trigeminal neuralgia is a painful unilateral affliction of the face, characterized by brief electric shock-like (lancinating) pains limited to the distribution of one or more divisions of the trigeminal nerve. Pain is commonly evoked by trivial stimuli (e.g., washing, shaving, smoking, talking, brushing the teeth) but also may occur spontaneously. Individual attacks are brief, lasting a few seconds to less than 2 minutes, and are stereotypic in the individual patient. The lightning-like pains and unilateral grimaces characteristic of trigeminal neuralgia led to the designation of the term *tic douloureux.* The diagnosis is straightforward in most patients on the basis of clinical criteria. However, because these symptoms also can be caused by an underlying mass lesion, CT or MRI is indicated in previously undiagnosed patients and when sensory loss or motor dysfunction is present.

Several drugs have been effective in treating trigeminal neuralgia, including carbamazepine, phenytoin, and baclofen; however, approximately 30% of patients fail to respond to medical therapy. In these patients, surgical management, by alcohol or glycerol injection or microvascular decompression, may be indicated.

Cough and Exertional Headache

In some patients, severe headache can be provoked by rapid increase in intra-abdominal pressure such as coughing, sneezing, laughing, heavy lifting or exertion, and the Valsalva maneuver. The pain starts within a few seconds of the precipitant and typically is brief when associated with cough but can last as long as 24 hours when associated with exertion. The headache is bilateral and throbbing in nature and in a majority of patients resolves spontaneously without persistent neurologic symptoms (e.g., neck stiffness or photophobia). In some patients, the headache may be secondary to structural lesions, especially in the posterior fossa; therefore, all previously undiagnosed patients require CT, or preferably MRI, followed by lumbar puncture to rule out intracranial disease including SAH. For patients with recurrent benign exertional headache, treatment includes avoidance of the underlying triggering mechanism and use of analgesics as necessary. For patients with exertional headache, NSAIDs including indomethacin have been effective.

Coital Headache

Coital cephalgia is a recurrent, benign headache associated with sexual activity and is more common in men than in women. Different types have been described, including headaches that occur before, during, or immediately after orgasm. They typically are occipital in location and may increase in severity with mounting sexual excitement. Their duration can be from minutes to hours. Occasionally, some patients experience a sudden, explosive headache that occurs during orgasm. In these patients, SAH should be ruled out.

High-Altitude Headache

Headache is one of the cardinal manifestations of acute mountain sickness and can occur at altitudes higher than 5000 feet above sea level in unacclimatized persons. The headache is throbbing in nature, located in the temporal or occipital areas, and probably is caused by a mild increase in ICP secondary to brain swelling. It is worse at night or in the early morning and exacerbated by the Valsalva maneuver or bending forward. Other findings associated with high-altitude illness include fatigue, nausea, vomiting, dizziness, insomnia, and an altered mental status. Pulmonary edema and cerebral edema develop in severe cases. The treatment for these conditions includes supplemental oxygen and descent to a lower altitude.

This chapter discusses cranial nerve problems, cerebral venous thrombosis, and multiple sclerosis—neurologic disorders that often provide significant diagnostic and therapeutic challenges in management in the emergency department (ED) setting (Table 103-1).

TRIGEMINAL NEURALGIA

Perspective

Trigeminal neuralgia, or tic douloureux, is a syndrome featuring painful paroxysms in one or more distributions of the trigeminal nerve. Trigeminal neuralgia is relatively uncommon, with an annual incidence of 4 to 13 cases per 100,000 population. It is more common in women than in men, with a female-to-male ratio of 1.7:1. Affected persons typically are between 50 and 69 years of age, and symptoms occur more frequently on the right side of the face.

Pathophysiology

Trigeminal neuralgia is an idiopathic disorder, although significant evidence points to vascular compression of the trigeminal nerve root in many cases. This compression commonly is caused by a tortuous arterial or venous loop in the posterior fossa, an arteriovenous malformation, or rarely a tumor. In surgical case series, vascular compression of the trigeminal nerve root is found in 80 to 90% of cases. Of note, however, structural lesions are not found in all patients with trigeminal neuralgia.

Clinical Features

Trigeminal neuralgia manifests with unilateral facial pain, typically characterized as lancinating paroxysms of pain in the lips, teeth, gums, or chin. The pain of trigeminal neuralgia commonly is associated with physical triggers such as chewing, brushing the teeth, shaving, or exposure to hot or cold temperature in the affected area. The maxillary and mandibular divisions of the trigeminal nerve are most commonly involved; rarely, the ophthalmic division alone is involved. Patients tend to experience the pain in clustered episodes that last a few seconds to several minutes. The attacks can occur during the day or night but rarely arise during sleep.

Diagnostic Strategies

A careful history and physical examination should be performed to rule out other painful facial conditions including odontogenic infections, sinus disease, otitis media, acute glaucoma, temporomandibular joint disease, and herpes zoster. Patients who lack local pathologic findings to explain the painful syndrome require a very careful neurologic examination. The presence of a neurologic deficit should prompt suspicion of a structural lesion, such as aneurysm, tumor, or other intracranial lesion such as from multiple sclerosis (MS). Of note, 2 to 4% of patients with trigeminal neuralgia also have MS. Patients with normal findings on the head and neck examination and no neurologic deficits who have episodic, unilateral facial pain associated with nonpainful triggers are likely to have trigeminal neuralgia.

Management

Since the 1960s the medical treatment of choice for trigeminal neuralgia has been use of the anticonvulsant carbamazepine. The purported effectiveness of this treatment is, however, based on uncontrolled studies, and the mechanism of action of anticonvulsant therapy for trigeminal neuralgia is unclear. The true efficacy of medical therapy is difficult to assess owing to a very high rate of spontaneous remission. Nonetheless, carbamazepine appears to be an effective and well-tolerated agent for treatment of trigeminal neuralgia. The initial dosage of carbamazepine is 100 mg twice daily; this dose is then increased to three times daily after one week. The dose may be increased by 100 mg per day, up to a maximum of 1200 mg per day. A complete blood count and liver function studies should be performed periodically in these patients to monitor for hematologic and hepatic side effects. Additional agents that have been used for treatment of trigeminal neuralgia include phenytoin, baclofen, valproate sodium, lamotrigine, and gabapentin. None of these drugs have been shown to be more effective than carbamazepine.

Surgical management has been a therapeutic option since the 1950s. Surgical procedures include both peripheral approaches and central procedures. Peripheral strategies include medication injection and cryotherapy techniques designed to temporarily block, or permanently ablate, branches of the peripheral trigeminal nerve. Although these procedures are relatively effective initially, recurrence is common. Repeated nerve

| Cranial nerve I: Olfactory nerve | Sense of smell | Unilateral anosmia | Trauma: Skull fracture or shear injury interrupting olfactory fibers traversing the cribriform plate  
Tumor: Frontal lobe masses compressing the nerve |
| Cranial nerve II: Optic nerve | Vision | Unilateral vision loss | Trauma: Traumatic optic neuropathy  
Tumor: Orbital compressive lesion  
Inflammatory: Optic neuritis (MS)  
Ischemic: Ischemic optic neuropathy |
| Cranial nerve III: Oculomotor nerve | Extraoculomotor function via motor fibers to levator palpebrae, superior rectus, medial rectus, inferior rectus, inferior oblique muscles  
Pupillary constriction via parasympathetic fibers to constrictor pupillae and ciliary muscles | Ptosis caused by loss of levator palpebrae function  
Eye deviated laterally and down  
Diplopia  
Dilated, nonreactive pupil  
Loss of accommodation | Trauma: Herniation of the temporal lobe through the tentorial opening causing compression and stretch injury to the nerve  
Ischemic: Especially in diabetes  
Microvascular ischemic injury to nerve causes extraocular muscle paralysis but usually is papillary-sparing (often painful)  
Vascular: Intracranial aneurysms may press on the nerve, leading to dysfunction  
Myasthenia gravis can lead to atraumatic ocular muscle palsy |
| Cranial nerve IV: Trochlear nerve | Motor supply to the superior oblique muscle | Inability to move eye downward and laterally  
Diplopia  
Patients tilt head toward unaffected eye to overcome inward rotation of affected eye | Trauma is the most common cause of nerve dysfunction |
| Cranial nerve V: Trigeminal nerve | Motor supply to muscles of mastication and to tensor tympani  
Sensory to face, scalp, oral cavity (including tongue and teeth) | Partial facial anesthesia  
Episodic, lancinating facial pain associated with benign triggers such as chewing, brushing teeth, light touch | Trauma:  
Facial bone fracture may injure one section, leading to area of facial anesthesia  
Tic douloureux |
| Cranial nerve VI: Abducens nerve | Motor supply to the lateral rectus muscle | Inability to move affected eye laterally  
Diplopia on attempting lateral gaze | Tumor: Lesions in the cerebellopontine angle  
Any lesion, vascular or otherwise, in the cavernous sinus may compress nerve  
Elevated intracranial pressure (ICP): Because of its position and long intracranial length, increased ICP from any cause may lead to injury and dysfunction of the nerve |
| Cranial nerve VII: Facial nerve | Motor supply to muscles of facial expression  
Parasympathetic stimulation of the lacrimal, submandibular, and sublingual glands  
Sensation to the ear canal and tympanic membrane | Hemifacial palsies:  
Lower motor neuron lesion leaves entire side of face paralyzed  
Upper motor neuron lesion leaves forehead musculature functioning  
Abnormal taste  
Sensory deficit around ear  
Intolerance to sudden loud noises  
Unilateral hearing loss  
Tinnitus  
Vertigo, unsteadiness | Lower motor neuron:  
Infection (viral): The likely cause of Bell’s palsy  
Lyne disease: The most common cause of bilateral cranial nerve VII palsy in areas where Lyme disease is endemic  
Bacterial infection extending from otitis media  
Upper motor neuron: Stroke, tumor  
Tumors: Acoustic neuroma  
Mimics Ménière’s disease, perilymphatic fistula |
| Cranial nerve VIII: Vestibulocochlear nerve | Hearing and balance | | |

Table 103-1 The Cranial Nerves: Normal Function and Pathologic Considerations—cont’d

blocks are not recommended owing to a high risk of permanent facial anesthesia.

Central procedures can be divided into percutaneous approaches and open approaches. Percutaneous destruction of the trigeminal ganglion can be done by means of radiofrequency ablation, thermal ablation, glycerol injection, or balloon microcompression. These procedures carry the risk of corneal anesthesia, oculomotor paresis, or masticatory weakness.9

Open surgical management is the surgical option of choice in most treatment centers. Open surgical procedures include microvascular decompression of the nerve with or without partial ablation. Although the open microvascular decompression procedure has proved to be very effective, with pain relief achieved in 80 to 95% of patients, the surgery is associated with the risk of significant complications, including hearing loss, facial anesthesia, cerebrospinal fluid leak, brainstem or cerebellar injury, headaches, meningitis, and death.10,11 Gamma knife radiosurgery, a minimally invasive, precision-directed stereotactic radiosurgery, also has been associated with good outcomes. This highly specialized technique requires extremely sophisticated stereotactic radiofrequency equipment and is available only in specialized centers.12,13

### KEY CONCEPTS

- Patients with unilateral, intermittent, lancinating facial pain without abnormalities on physical examination are likely to have trigeminal neuralgia.
- Carbamazepine is the first-line agent for medical treatment.
- Patients who do not tolerate or whose pain is refractory to medical management may be candidates for microvascular decompression or ablation.

### FACIAL NERVE PARALYSIS

#### Perspective

The acute onset of facial nerve paralysis often will prompt an ED visit, when early diagnosis and therapy can improve the patient’s chance for recovery of function of the facial nerve. Facial nerve paralysis of acute onset affects approximately 20 to 25 persons per 100,000 population per year, without geographic, gender, or race predilection.14,15

#### Principles of Disease

The facial nerve innervates the muscles of facial expression and the muscles of the scalp and external ear, in addition to the buccinator, platysma, stapedius, stylohyoid, and posterior belly of the digastric muscles. The sensory portion of the nerve supplies the anterior two thirds of the tongue with taste and...
sensation to portions of the external auditory meatus, soft palate, and adjacent pharynx. The parasympathetic portion supplies secretomotor fibers for the submandibular, sublingual, lacrimal, nasal, and palatine glands.\(^{16}\)

The nerve originates from the pontomedullary junction of the brainstem. The nerve enters the internal auditory meatus with cranial nerve VIII. Within the temporal bone the facial nerve has four major branches: the greater and lesser superfi
cial petrosal nerves, the nerve to the stapedius muscle, and the chorda tympani. The facial nerve exits the temporal bone at the stylomastoid foramen. The nerve then enters the parotid gland, where it divides to supply the muscles of facial expression.\(^{16,17}\)

**Pathophysiology**

Although a complete list of possibilities in the differential diagnosis for facial nerve paralysis would be a long one, the causes pertinent to emergency medicine can be grouped into three specific categories: infectious, traumatic, and neoplastic.

**Infection**

**Bell’s Palsy**

Bell’s palsy, also commonly called *idiopathic facial paralysis*, has long been postulated to have a viral cause. This disease entity is characterized by an abrupt onset of a lower motor neuron paresis that can progress over 1 to 7 days to complete paralysis. A prodromal illness is described by 60% of patients. Symptoms and signs frequently associated with the facial paresis include ear pain, a perception of sensory change on the involved side of the face, decreased tearing, an overflow of tears on the cheek (epiphora), abnormally acute hearing (hyperacusis), and an impairment or perversion of taste (dysgeusia).\(^{18}\)

Treatment approaches can be medical or surgical. The primary medical therapies for Bell’s palsy center on reducing inflammatory changes to the nerve with corticosteroids and treating the presumed viral cause. If these therapies are unsuccessful then surgical decompression may be considered.

The use of corticosteroids for Bell’s palsy has been controversial. The rationale for this application of steroid therapy is that edema of the nerve, confined within the facial canal, is thought to cause or contribute to the nerve injury. On the basis of this theory, most experts currently recommend a course of prednisone with an initial dose of 1 mg/kg per day for 7 to 10 days, with or without a short taper.\(^{14,17,19,20}\) The most definitive randomized, double-blind, placebo-controlled trial involving 496 patients showed an improvement in complete recovery of facial nerve function at 3 months from 64% with placebo to 83% with the use of prednisolone in a dose of 25 mg by mouth twice daily.\(^{21}\) Therapy should be started as soon as possible, ideally within the first 24 hours, but is still recommended for patients without contraindications who seek treatment within 1 week of symptom onset.\(^{19}\)

A number of publications have advanced the belief that Bell’s palsy may be caused by herpesvirus infection. One study demonstrated herpes simplex virus type 1 DNA in the endoneural tissue of 11 of 14 patients with Bell’s palsy but not in that of control subjects.\(^{22}\) In a trial of prednisone and acyclovir in 99 patients, patients treated with prednisone and acyclovir had a more favorable recovery than that observed in patients receiving prednisone alone.\(^{23}\) A study of 296 patients with Bell’s palsy treated with valacyclovir or placebo in addition to a fixed dose of prednisolone found significant benefit to the addition of valacyclovir, particularly in the setting of severe palsy or in those treated within 24 hours of symptom onset.\(^{24}\) Other studies have found conflicting results. Despite a lack of overwhelming evidence, the addition of an antiviral agent should be considered in the treatment of Bell’s palsy, especially with severe loss of function. The most commonly recommended antiviral regimens include valacyclovir, 1000 mg orally two times daily for 10 days. Valacyclovir and famciclovir have better oral absorption, are better tolerated, and are dosed less frequently, resulting in higher compliance. Accordingly, they have been recommended as alternatives to acyclovir.\(^{17,19,20,22,25}\) As with steroid therapy, although earlier treatment is preferred, treatment should be considered for patients presenting within 1 week of symptom onset.

**Ramsay Hunt Syndrome**

Ramsay Hunt syndrome (herpes zoster oticus) is characterized by unilateral facial paralysis, a herpetiform vesicular eruption, and vestibulocochlear dysfunction. The vesicular eruption may occur on the pinna, external auditory canal, tympanic membrane, soft palate, oral cavity, face, and neck as far down as the shoulder. The pain is considerably more severe than that associated with Bell’s palsy, and it frequently is out of proportion to physical findings. In addition, outcomes are worse than with Bell’s palsy, with a lower incidence of complete facial recovery and the possibility of sensorineural hearing loss. Therapy is similar to that for Bell’s palsy. Both prednisone and antiviral therapy for 7 to 10 days are advocated.\(^{17,26,27}\)

**Lyme Disease**

Lyme disease is the most frequent vector-borne infection in the United States. It is caused by the spirochete *Borrelia burgdorferi* and is spread by the bite of *Ixodes* genus ticks. Neurologic manifestations can arise in any phase of the disease, and the incidence of facial palsy in patients with neurologic involvement is 35 to 51%. In regions in which Lyme disease is endemic, it has been shown to be the leading cause of facial paralysis in children, responsible for one half of all pediatric cases of facial nerve paralysis.\(^{28,29}\)

Bilateral facial nerve paralysis is rare but can occur with systemic infections. The two diseases most commonly associated with bilateral simultaneous onset of facial paralysis are Lyme disease and infectious mononucleosis. Bilateral facial paralysis should be considered to be a manifestation of Lyme disease until further testing excludes this diagnosis.\(^{30,28-36}\) The evaluation and treatment of Lyme disease are discussed in Chapter 132.

**Bacterial Infections**

Facial paralysis can be caused by acute bacterial infections of the middle ear, mastoid, or external auditory canal. In the preantibiotic era, facial paralysis was associated with acute otitis media in approximately 2% of cases; today, however, it occurs in only 0.2% of cases. Treatment consists of intravenous antibiotics and myringotomy for decompression. Malignant otitis externa can be associated with facial paralysis. This disease entity is most commonly seen in immunocompromised patients and usually is caused by *Pseudomonas* infection. Treatment involves prolonged intravenous antibiotic therapy and may require surgical débridement.\(^{20,31}\)

**Trauma**

In patients with head trauma, the facial nerve is the most commonly injured cranial nerve. The cause generally is a temporal bone fracture with nerve transection. Surgical exploration is warranted if there is firm evidence that the nerve has been transected, indicated by a sudden onset of complete unilateral facial paralysis, loss of electrical activity, and evidence of a displaced fracture involving the facial canal.
Neoplasm

Tumors of the facial nerve itself, or tumors anywhere along the course of the facial nerve that invade or compress the nerve, may lead to facial paralysis. Typically the course is progressive over at least 3 weeks. A sudden onset of paralysis, however, does not rule out an underlying tumor, because facial paralysis secondary to a neoplasm is of sudden onset in approximately 25% of cases.32 A neoplastic cause should be suspected in patients who suffer from recurrent ipsilateral facial paralysis, significant pain, prolonged symptoms, or any other concomitant cranial nerve abnormality.

Clinical Features and Differential Considerations

The medical history should focus on onset of the paralysis, concentrating on timing and rapidity of onset and looking for any associated signs and symptoms. A rapid onset of facial paralysis with dysgeusia and hyperacusis preceded by a viral prodrome is suggestive of Bell’s palsy. A history of recurrent ipsilateral paralysis or slow progression of symptoms is more characteristic for a tumor. Associated cranial nerve abnormalities, although occasionally seen with Bell’s palsy, also point to the possibility of a tumor or ischemic insult. The Ramsay Hunt syndrome causes significant pain and a vesicular rash, although the rash may follow the facial paresis by a few days. Significant anatomic abnormalities on visual or otoscopic inspection of the ipsilateral ear will be found with bacterial otitis media and otitis externa. Finally, systemic symptoms or bilateral facial paresis, especially in endemic areas, should raise the possibility of Lyme disease.

Diagnostic Strategies

The diagnostic workup of acute facial nerve paresis is based on whether the clinical picture is suggestive of a disease process other than Bell’s palsy. If the clinical history is classic for Bell’s palsy, then no imaging or laboratory studies are required. Of note, any history of possible exposure warrants serologic evaluation for Lyme disease. Although outpatient testing including electroneurography may ultimately be performed, this usually is not part of the initial evaluation.

The physical examination finding of a “central” seventh nerve paralysis (upper face–sparing) should prompt imaging with computed tomography (CT) or MRI, and consideration should be given to the possibility of an acute stroke or other hemispheric lesion. History or physical examination findings suggestive of a possible tumor require imaging to rule out a neoplasm. The study of choice will depend on the institution and preferences of the consultant.

Disposition

The vast majority of patients who have a seventh nerve paralysis will have a clinical diagnosis of Bell’s palsy and may be discharged with referral for short-term follow-up. Patients with a possible hemispheric process such as stroke or tumor should be hospitalized for further evaluation. Patients suspected of having Lyme disease require immediate initiation of appropriate antibiotic therapy.

In patients with a peripheral facial nerve paralysis, the ipsilateral eye should be patched, and consideration should be given to ophthalmologic follow-up, because there is a high rate of corneal abrasions and corneal dryness associated with the inability to properly blink or completely close the eye.

KEY CONCEPTS

- Recent literature highlights significant potential benefit for patients with clinical evidence of Bell’s palsy when they are treated early in the course with corticosteroids. The additional benefit of adding antiviral medication is controversial, but this treatment probably is warranted in patients with severe loss of function.
- Slowly progressive facial paralysis is suggestive of a neoplasm. Recurrent unilateral paralysis may occur with Bell’s palsy but frequently (30%) is seen in patients with tumor.
- Simultaneous bilateral facial paralysis is suggestive of Lyme disease, which must be considered as a possible cause, especially in endemic regions.
- Patients who have facial muscle paresis with intact forehead movement should be considered to have an upper motor neuron lesion until the diagnostic investigation proves otherwise.

■ VESTIBULAR SCHWANNOMA

Perspective

Vestibular schwannoma, formally referred to as acoustic neuroma, is a rare but important cause of sensorineural hearing loss. The annual incidence of VS is 1 case per 100,000 population, with a mean age at the time of detection of 46 to 58 years.33 The female-to-male ratio is 1.5:1. Vestibular schwannoma is very rarely bilateral, occurring in this form in approximately 5% of cases and generally associated with type II neurofibromatosis. Although histologically benign, vestibular schwannoma can cause neurologic damage by direct compression on the eighth cranial nerve and the other structures in the cerebellopontine angle.34

Principles of Disease

Vestibular schwannoma arises from the Schwann cells covering the vestibular branch of the eighth cranial nerve as it passes through the internal auditory canal. The tumor may compress the cochlear (acoustic) branch of the eighth cranial nerve, causing hearing loss, tinnitus, and dysequilibrium. Continued growth of the tumor may result in compression of structures in the cerebellopontine angle, where the facial and trigeminal nerves may be compressed and damaged. Larger tumors may further encroach upon the brainstem and if large enough may compress the fourth ventricle, ultimately resulting in signs of increased intracranial pressure (ICP).35

Clinical Features

Asymmetrical sensorineural hearing loss is the hallmark of vestibular schwannoma. Up to 15% of patients with this tumor, however, will have normal results on an audiogram. These patients typically have symptoms such as unilateral tinnitus, imbalance, headache, fullness in the ear, otalgia, or facial nerve weakness. Thus, patients with asymmetrical symptoms should be further evaluated for vestibular schwannoma even with normal findings on the audiogram.36 Vestibular schwannomas are extremely slow-growing tumors, averaging an approximately 1-mm increase per year, although many do not grow at all on serial examinations.37 Symptom onset is therefore generally quite gradual. In one series of 126 cases, the average time from symptom onset to discovery of a vestibular schwannoma was approximately 4 years.38
Diagnostic Strategies

When vestibular schwannoma is suspected, the patient should be evaluated with an audiogram or a gadolinium-enhanced MRI. This imaging technique is extremely sensitive and has led to earlier diagnosis and a decrease in mean size at detection of vestibular schwannoma. CT lacks the necessary sensitivity in the posterior cranial fossa to reliably rule out the presence of vestibular schwannoma. The smaller the tumor at the time of diagnosis, the more options there are for therapy and the better the potential prognosis.34

Differential Considerations

A majority of disease entities included in the differential diagnosis for acoustic neuroma cause symmetrical sensorineural hearing loss. Asymmetrical sensorineural hearing loss has few causes other than vestibular schwannoma. Ménérette’s disease may present a diagnostic dilemma because it can be asymmetrical. Ménérette’s disease may be differentiated from vestibular schwannoma in that the tinnitus of Ménérette’s disease is usually intermittent, whereas the tinnitus of vestibular schwannoma typically is continuous. In addition, patients with Ménérette’s disease typically describe true vertigo, whereas patients with a vestibular schwannoma are more likely to describe imbalance or dysequilibrium.

Vestibular schwannomas account for 80% of all cerebellopontine angle tumors. Among all other lesions, meningioma is the most common. Meningiomas more frequently cause symptoms of facial palsy or trigeminal nerve abnormality. Of note, however, considerable similarity between the clinical picture of a meningioma and that of vestibular schwannoma in the cerebellopontine angle has been described.39

Management

Vestibular schwannoma may be removed surgically or ablated with stereotactic radiation. In general, tumors larger than 3 cm are recommended for microsurgery, because radiation treatments, such as with the Gamma Knife or linear accelerator, are less effective for local control and growth arrest in larger masses. Smaller tumors are amenable to use of stereotactic radiation, which may have greater salvage rates of facial nerve function and hearing. Stereotactic radiation therapy generally has good long-term outcomes of local growth arrest, with nerve salvage approaching 90% or greater. Injuries to the trigeminal, facial, and acoustic nerves, and to the cerebellum, are possible complications of both procedures. In patients who are minimally symptomatic with small tumors, serial monitoring with MRI is a viable nonsurgical option. All patients should be evaluated by a specialist in the evaluation and treatment of vestibular schwannoma, because smaller tumor size at detection is associated with a better long-term outcome.35,37

Disposition

Patients with suspected acoustic neuroma should be referred for an audiogram or MRI and evaluation by a specialist in either otolaryngology or neurosurgery.

DIABETIC CRANIAL MONONEUROPATHY

Perspective

Cranial mononeuropathies occur uncommonly, usually are a complication of diabetes, and most often affect the extraocular muscles. The oculomotor nerve is most commonly affected, followed in order by the trochlear and abducens nerves. In one large series in Japan, the incidence of cranial nerve palsies was 1.0% among diabetics and 0.1% among nondiabetics.40,41 Whereas ophthalmoplegia appears to be closely related to diabetes, facial palsy is less strongly correlated with this disease.40

Principles of Disease

The pathologic basis of diabetic mononeuropathy appears to be ischemia of the affected cranial nerve caused by occlusion of an intraneural nutrient artery serving the nerve. This occlusion leads to injury located primarily in the center of the nerve, because the core fibers are more dependent on the supply from such nutrient arteries. The peripheral fibers are less affected because they also are supplied by collateral vessels. In the oculomotor nerve, the preservation of the circumferentially located parasympathetic fibers explains the pupillary sparing that usually is found in this syndrome. In two studies, the microvascular changes in the intraneurites that lead to occlusion were noted in diabetic patients but absent in nondiabetics.42,43

Clinical Features

Patients typically describe acute onset of unilateral retro-ocular pain, diplopia, and ptosis.41 The physical manifestations of a third cranial nerve palsy include the inability to move the eye superiorly and medially, accompanied by ptosis. The pupillary light reflex usually is present. Although a less common finding, the fourth and sixth cranial nerves may be affected. Patients with a fourth cranial nerve palsy are unable to move the eye inferolaterally, and those with a sixth cranial nerve palsy are unable to move the eye laterally. Because of the long intracranial course of the sixth nerve, a patient with an isolated sixth nerve palsy should be evaluated for an intracranial lesion or increased ICP.44

Differential Considerations

Evaluating cranial nerve dysfunction requires a thorough history and physical examination and cranial imaging, usually with MRI. Diabetic mononeuropathy should be considered a diagnosis of exclusion, with considerations in the differential diagnosis including trauma, tumor, vertebrobasilar ischemia, aneurysm, and hemorrhage into the brainstem.45

Management

Treatment consists of patching the affected eye and administration of analgesics and antiplatelet therapy. The prognosis is good. If the neuropathy does not begin to resolve within 3 to 6 months, or if more than one nerve is affected, another cause should be sought. Complete resolution is expected within the first year. Antioxidant preparations, including α-lipoic acid, have been used therapeutically and have not shown harm, but
such agents have yet to be shown to have convincing clinical effect.46

KEY CONCEPTS

- Diabetic neuropathy is a diagnosis of exclusion because no definitive diagnostic testing is available.
- Both ischemic and hemorrhagic brainstem lesions must be ruled out in the case of an acute ophthalmoplegia.
- Extraocular mononeuropathy is sufficiently common in patients with diabetes mellitus that its occurrence in isolation warrants evaluation of the patient for previously undiagnosed diabetes.

CEREBRAL VENOUS THROMBOSIS

Perspective

No precise studies of the epidemiology of cerebral venous thrombosis (CVT) have been performed. In case series, the median patient age is approximately 37 years, with a female-to-male ratio of 3:1.47

Principles of Disease

Cerebral blood is drained by several major veins that lead into the dural sinuses. The major dural sinuses are the superior sagittal sinus, the inferior sagittal sinus, the straight sinus, the lateral sinuses, and the sigmoid sinuses. The variability in symptoms and signs in patients who present with CVT stems from differences in thrombus location and acuity of thrombus formation. Symptoms of intracranial hypertension are present in most patients with sinus thrombosis, whereas those with thrombosis of the cerebral veins are thought to be more prone to hemorrhagic infarction and localizing neurologic deficits.48 As with venous thrombosis in other locations, multiple causes and predisposing factors for CVT are recognized. Underlying causes often are divided into infectious and noninfectious categories. Infectious causes include local infections, such as sinusitis, otitis media, cellulitis on the face, and systemic infections. Noninfectious causes include direct injury to the cerebral venous system from trauma, surgery, tumor, dehydration, or any other condition that may predispose the patient to previously undiagnosed diabetes.49

Clinical Features

The symptoms and signs associated with CVT are quite varied. Headache is the primary feature of CVT in 74 to 92% of affected patients.49,50 Papilledema is noted in 28 to 45% of cases.47 Lethargy, decreased level of consciousness, or mental status changes may be noted. Seizures occur in 35 to 50% of patients in the acute phase.47,49,51 In addition to the location and acuity of thrombosis formation, a patient’s symptom onset will vary in accordance with the extent of collateral vessel growth in the venous territory. Early thrombotic changes may be well compensated for by the collateral venous drainage. Symptoms will appear only when the compensation for venous thrombosis is no longer sufficient. Variability in collateralization between patients also adds to the variability and time course of symptomatology. Two national and international observational studies document an average time from symptom onset to diagnosis of 7 days, reflecting the difficulty in diagnosing this rare disease entity.47,52 The reported incidence of focal neurologic signs, including seizures, on clinical examination varies between series, ranging from 25 to 71%.49,50 Because of the broad spectrum of possible clinical features, the diagnosis of CVT may be difficult but should be a consideration in any patient with unexplained headache, especially in combination with focal neurologic deficit, papilledema, or seizures.

Diagnostic Strategies

The gold standard modality for the diagnosis of CVT has shifted in recent years from cerebral angiography to magnetic resonance venography (MRV). CT scanning is useful in the initial workup of the patient with possible CVT, but noncontrast CT is neither sensitive nor specific enough to reliably confirm or exclude the diagnosis. Findings on CT that are consistent with CVT include hyperdensity of a thrombosed sinus, brain edema, and hemorrhage secondary to venous congestion. CT venography is both more sensitive and more specific in diagnosing CVT.

Similar to CT scanning, MRI also can demonstrate local changes secondary to venous congestion, such as brain edema or hemorrhage. In addition, MRI can demonstrate the possibility of CVT based on the lack of a “flow void.” On conventional MRI, a flow void indicates the presence of blood flow within the sinus, whereas the absence of a flow void indicates a possible thrombus. Diagnostic accuracy, however, is greatly improved through use of MRV. This technique takes advantage of the MRI signal characteristics of flowing blood to create images of venous structures. Combining these imaging techniques further enhances diagnostic accuracy. For imaging a particular dural sinus, presence of the sinus on conventional MRI and lack of flow on MRV are diagnostic of a sinus thrombosis. This combined approach has diagnostic sensitivity similar to that of conventional angiography.49,53

Two small studies show similar sensitivity between MRV and CT venography for the diagnosis of CVT when the CT study is performed on a multidetector row CT scanner. Both studies, involving a total of 69 patients, showed 100% sensitivity of CT venography for CVT in comparison with MRV.54,55 The sensitivity of CT venography performed by scanners that do not use multidetector row technology is unknown.

Several small studies have attempted to evaluate the usefulness of the D-dimer assay as a screening tool to exclude CVT, particularly when MRI or CT venography is not available. Although the reported sensitivity rates are fair at 83 to 100%, larger prospective studies need to be done to further define the role of D-dimer in the evaluation of CVT, because several case reports have noted normal D-dimer levels in the setting of documented CVT.56-59 In general, although a normal D-dimer level does not exclude the diagnosis of CVT, it does appear to make this diagnosis much less likely, particularly in a patient with symptoms of less than 2 weeks in duration.

Differential Considerations

Considerations in the differential diagnosis of CVT include the conditions that cause patients to present with the new onset of neurologic deficits, alteration in consciousness, or severe headache. A diagnosis of CVT should be considered in a patient with such symptoms when the etiology is unclear, presence of having a hypercoagulable state is likely, and the head CT scan is normal in appearance or shows subtle signs of CVT.

Management

CVT is a relatively rare disease, and controlled studies evaluating its treatment are lacking. Current therapeutic consensus
strongly recommends systemic anticoagulation with low-molecular-weight or unfractionated heparin to prevent further clot formation and to promote recanalization, even in patients with intracranial hemorrhage on initial imaging. In one placebo-controlled randomized trial comprising 20 patients, anticoagulation with heparin to a target partial thromboplastin time (PTT) of 80 to 100 seconds demonstrated benefit, even in patients in which evidence of intracranial hemorrhage was seen on the CT scan before anticoagulation. In another study of 60 patients randomized to receive placebo or low-molecular-weight heparin, no statistical benefit was shown for treatment. Two large observational trials showed improvement in modified Rankin scale at follow-up in the anticoagulated groups, although the trials were not randomized. Despite a paucity of randomized controlled trials, expert opinion favors anticoagulation in all groups unless another contraindication is present. Catheter-based intervention with thrombolysis has been attempted in multiple case series using either urokinase or tissue plasminogen activator. Thrombolysis was shown to be relatively safe and relatively successful in very small case series. In one nonrandomized study of 40 patients, 20 received systemic heparin and 20 received catheter-based infusion of urokinase followed by systemic heparin. Despite initially worse neurologic function in the thrombolysis group, a significant difference in neurologic function favoring thrombolysis was observed at discharge. Although this therapy is promising, it should be considered only for patients with symptoms of decreased level of consciousness, elevated ICP, or rapid deterioration on neurologic examination.

**Disposition**

All patients with suspected CVT should be admitted to a unit capable of providing a high level of care with neurologic consultation. Patients should be anticoagulated if no contraindication exists, and catheter-based thrombolysis should be considered in patients with depressed mental status or focal findings on neurologic exam.

---

**KEY CONCEPTS**

- CVT is a relatively rare entity, and only awareness of and familiarity with the clinical presentation will lead to the correct diagnosis.
- The onset may be insidious with a considerable delay between onset and arrival in the treatment setting.
- The differential diagnosis for CVT should consider other conditions that cause patients to present with new-onset neurologic deficits, alteration in consciousness, or severe headache. CVT is more likely to be present in such patients when the etiology is unclear, the patient is suspected of having a hypercoagulable state, and the head CT is normal in appearance or shows subtle signs of CVT.
- Noncontrast CT scanning is not adequate to rule out CVT. An MRI with MRV is recommended, although multidetector row CT venography is an acceptable alternative.
- Treatment of most patients with CVT should include systemic anticoagulation, even in the setting of hemorrhagic cerebral infarcts, unless another contraindication exists.

---

**MULTIPLE SCLEROSIS**

**Perspective**

Multiple sclerosis (MS) is an inflammatory disease that affects the central nervous system (CNS). Although the exact etiology remains uncertain, the pathologic manifestation of this inflammatory disease is a demyelination of discrete regions (plaques) within the CNS with a relative sparing of axons. The clinical picture is highly variable but is classically characterized by episodes of neurologic dysfunction that evolve over days and resolve over weeks.

MS has an overall prevalence in the United States of 0.1%. The peak age at onset is 25 to 30 years, with women being slightly younger at onset than men. The incidence in women exceeds that of men by a ratio of 1.8 : 1. The worldwide prevalence is greatest in the United Kingdom, Scandinavia, and North America. Epidemiologic studies indicate that both genetic and environmental factors are associated with an increased incidence of this disease. MS has a 30% concordance rate between monozygotic twins, and 20% of patients with MS have at least one affected relative. MS is more common in temperate climates. It is rare between 23 degrees north and south latitudes but has a rising incidence above and below 50 degrees north and south latitudes, respectively. Although no exact environmental factor has been identified, if a person emigrates from an area of high prevalence to an area of low prevalence before the age of 20, the risk is diminished. MS is rare in Africans and Asians, but African Americans have a higher incidence than their relatives who remain in Africa. In addition, reports of clusters or miniepidemics support environmental factors. Thus, an environmental cause superimposed on genetic susceptibility appears to be a likely etiologic scenario.

**Principles of Disease**

MS is considered to be an organ-specific autoimmune disease. One theory proposes that genetic factors interact with an environmental trigger or infection to establish pathologically auto-reactive T cells in the CNS. After a long and variable latency period (typically 10 to 20 years), a systemic trigger, such as a viral infection or superantigen, activates these T cells. The activated T cells, on reexposure to the autoantigen, initiate the inflammatory response. This sets off a complex immunologic cascade that leads to the demyelination characteristic of MS. This demyelination process releases CNS antigens that are hypothesized to initiate further episodes of autoimmune-induced inflammation. The mechanisms underlying this autoimmunity in MS are unknown.

**Clinical Features**

The clinical picture in MS is one of marked heterogeneity. The classic clinical syndrome consists of recurring episodes of neurologic symptoms that rapidly evolve over days and slowly resolve. Variability occurs in age at onset, location of CNS lesions, frequency and severity of relapses, and the degree and time course of progression.

The clinical features of MS can be divided into areas of specific CNS impairment: cognition, cranial nerves, motor pathways, sensory pathways, cerebellar pathways, and bowel, bladder, and sexual dysfunction.

Patients with MS have frequent complaints of poor memory, distractibility, and a decreased capacity for sustained mental effort. Formal neuropsychological testing suggests that cognitive involvement is common and underreported. Specifically,
neuropsychological testing has shown that 43 to 65% of patients with MS have some degree of cognitive impairment. Of note, a correlation has been found between the MRI-based total lesion load and presence of cognitive impairment.

Cranial nerve dysfunction is common in MS. The most common associated cranial nerve abnormality is optic neuritis, a unilateral syndrome characterized by pain in the eye and a variable degree of visual loss affecting primarily central vision. Within 2 years of an attack of optic neuritis, the risk of MS is approximately 20%, and within 15 years, it is approximately 45 to 80%. Optic neuritis often is the first symptom of MS.

As a result of lesions in the vestibulo-ocular connections, the oculomotor pathways also may be affected. The deficit may manifest as diplopia or nystagmus. The nystagmus may be severe enough that the patient may complain of oscillopsia (a subjective oscillation of objects in the visual field). Cranial nerve impairment also may include impairment of facial sensation, which is relatively common. Unilateral facial paresis also may occur. In addition, the occurrence of trigeminal neuralgia in a young person may be an early sign of MS.

Motor pathways also are commonly involved. Specifically, corticospinal tract dysfunction is common in patients with MS. Paraparesis or paraplegia is all too common and occurs with greater frequency than upper extremity lesions, owing to the common occurrence of lesions in the motor tracts of the spinal cord. In patients with significant motor weakness, spasms of the legs and trunk may occur on attempts to stand from a seated position. This dysfunction is manifested on physical examination as spasticity that typically is worse in the legs than in the arms. The deep tendon reflexes are markedly exaggerated, and sustained clonus may be demonstrated. Although these symptoms frequently are bilateral, they generally are asymmetrical.

Sensory manifestations are a frequent initial feature of MS and will be present in nearly all patients at some point during the course of the disease. Sensory symptoms are commonly described as numbness, tingling, “pins and needles” paresthesias, coldness, or a sensation of swelling of the limbs or trunk.

Impairment of the cerebellar pathway results in significant gait imbalance, difficulty with coordinated actions, and dysarthria. Physical examination reveals the typical features of cerebellar dysfunction, including dysmetria, dysdiadochokinesis (an impairment of rapid alternating movements), a breakdown in the ability to perform complex movements, an intention tremor in the limbs and head, truncal ataxia, and dysarthria.

Impairment of bowel, bladder, and sexual function also is common. The extent of sphincter and sexual dysfunction usually parallels the motor impairment in the lower extremities. Urinary frequency may progress to urinary incontinence with progression of the disease. An atomic bladder may develop, which empties by simple overflow and often is associated with the loss of perception of bladder fullness and with anal and genital hypoesthesia. Constipation becomes common over time, and almost all patients with paraplegia require special measures to maintain effective bowel habits. Sexual dysfunction, although frequently overlooked, is very common in MS. Approximately 50% of patients become completely sexually inactive as a result of this disease.

### Diagnostic Strategies

Although no laboratory tests are diagnostic for MS, one clinical feature remains relatively unique to this disease: Uhthoff’s phenomenon, temporary worsening of current or preexisting signs or symptoms of MS secondary to small increases in the patient’s body temperature. Accordingly, exercise, a hot bath, exposure to a warm environment, or fever can bring about Uhthoff’s phenomenon. This phenomenon reflects subclinical demyelination or preexisting injury to nerves without obvious significant clinical involvement before heat exposure or temperature elevation.

The clinical diagnosis rests on occurrence of at least two clinical episodes with different neurologic symptoms at different times. Thus, MS commonly has been characterized as a disorder with lesions that differ in time and space. It also has been described as a relapsing-remitting disorder with symptoms that fluctuate over time.

Findings on cerebrospinal fluid (CSF) analysis are abnormal in 90% of the cases. Fifty percent of patients will have pleocytosis, with more than 5 lymphocytes per high-power field in the CSF. Approximately 70% of patients will have an elevated gamma globulin level, with immunoglobulin G (IgG) ranging from 10 to 30% of the CSF total protein. Electrophoresis of the CSF demonstrates oligoclonal bands of IgG in 85 to 95% of patients who carry a diagnosis of MS; however, oligoclonal bands of IgG also are seen with neurosyphilis, fungal meningitis, and other CNS infections. Lumbar puncture should be considered for all patients with suspected MS, but mass lesions and elevated ICP should be ruled out before lumbar puncture.

The initial imaging test to aid in the diagnosis of multiple sclerosis is MRI. MRI is a sensitive test for the detection of lesions consistent with MS and also is useful to assess disease severity. The lesions of MS typically appear hyperintense, or bright white, on T2-weighted or fluid-attenuated inversion recovery (FLAIR) MRI studies. Lesions usually are multiple and commonly are found in the periventricular white matter.

In patients with an initial neurologic event consistent with CNS demyelination and an MRI cranial study showing multiple white matter lesions, the 5-year risk of developing MS is 60%. Patients with similar clinical syndromes and a normal MRI appearance have less than a 5% 5-year risk.

### Differential Considerations

Other diseases that affect the CNS white matter may be clinically and radiographically similar to MS. Considerable care must be taken to exclude these disease processes before making a diagnosis. These include CNS tumors (especially lymphomas and gliomas), spinal cord compression, vasculitides, Behçet’s disease, neurosarcoidosis, postinfectious and postvaccinal encephalomyelitis, human immunodeficiency virus (HIV) encephalopathy, Lyme disease, and vitamin B12 deficiency.

### Management

Management of patients with MS has essentially three aspects: (1) therapies aimed at halting the progression of the disease, (2) treatment for acute exacerbations, and (3) therapies designed to modify complications.

Therapies aimed at halting disease progress are based primarily on the use of either β-interferon or glatiramer acetate. The interferons are a group of natural compounds with antiviral and immunomodulatory actions, which are retained by the recombinant preparations used in therapy for MS, interferon beta-1a and interferon beta-1b. Side effects include flulike symptoms, depression, anxiety, and confusion. In one study, 560 patients with MS were randomly assigned to receive subcutaneous interferon beta-1a or placebo (n = 187) three times a week for 2 years. The relapse rate was significantly lower at 1 and 2 years with interferon beta-1a than with placebo. The time to first relapse was prolonged significantly and the accu-
mulation of brain lesions on MRI was lower in the treatment group than in the placebo group. The investigators concluded that subcutaneous interferon beta-1a is a well-tolerated and effective treatment for relapsing-remitting MS in terms of relapse rate, defined disability, and all MRI outcome measures. β-interferon also has been shown to retard progression to clinically definite MS and to decrease the total number of brain lesions seen on subsequent MRI studies in patients who have their first demyelinating episode with MRI abnormalities at initial presentation. This finding highlights the importance of early evaluation and treatment.

Glatiramer acetate also has successfully been used in the treatment of MS. This agent is a mixture of synthetic polypeptides designed to mimic myelin basic protein. The mechanism of action by which glatiramer acetate exerts its effect is unknown, but it is thought to modify the immune processes responsible for the pathogenesis of MS. In one study, 251 patients with relapsing-remitting MS were randomized to receive daily subcutaneous injections of glatiramer acetate (previously called copolymer 1) or placebo for 24 months. Patients receiving glatiramer acetate experienced significantly fewer relapses and were more likely to demonstrate neurologic improvement, whereas those receiving placebo were more likely to worsen. This drug generally is quite well tolerated.

Current recommendations for management of relapsing-remitting MS are to initiate treatment with β-interferon or glatiramer acetate. Such regimens have been demonstrated to decrease the volume of plaques seen on MRI and to diminish relapses. Immunosuppressive agents, including mitoxantrone and azathioprine, also have been shown to be effective in reducing progression of disease but, in view of concerns over side effects, generally are used as second-line agents.

Acute exacerbations of MS also should be targets for therapy. Although most such episodes will resolve without therapy, steroids have been demonstrated to diminish the duration of acute exacerbations. More than 85% of patients with relapsing-remitting MS show improvement with intravenous methylprednisolone. Intravenous steroids have been demonstrated to diminish the duration of acute exacerbations. More than 85% of patients with relapsing-remitting MS show improvement with intravenous methylprednisolone. Intravenous steroids have been shown in controlled trials to speed the recovery from the visual loss of optic neuritis when compared with placebo. In addition, when patients with acute optic neuritis are treated with high-dose intravenous steroids, the 2-year rate of development of MS is reduced, although this effect diminishes over time. Of interest, oral prednisone was not found to be helpful in the optic neuritis trials and was associated with a potential increase in the number of optic neuritis episodes.

The current standard therapy for an acute exacerbation in MS is intravenous methylprednisolone. A typical dose administered intravenously is 250 to 500 mg every 12 hours for 3 to 7 days. Whether this should be followed by an oral prednisolonelone taper remains controversial. Potential adverse effects of methylprednisolone therapy include fluid retention, gastrointestinal hemorrhage, anxiety, psychosis, infection, and osteoporosis. Several therapies directed toward the complications of MS may be helpful. The associated spasticity generally is treated with baclofen. This is a highly effective therapy aimed at reducing the painful flexor and extensor spasms. A major side effect is drowsiness, which generally diminishes with continued use. Higher-dose therapy can cause confusion, especially in the setting of baseline cognitive impairment. For patients with intractable spasticity, baclofen is available for intrathecal administration by either bolus therapy or continuous implanted pump therapy. Additional therapeutic agents for control of spasticity include tizanidine, diazepam, and dantrolene.

The tremor and ataxia associated with MS occasionally are treated with propranolol, diazepam, or clonazepam. The results of these therapies, however, generally are unsatisfactory. Pain often is associated with MS and affects the shoulders, pelvic girdle, and face. The facial pain may be indistinguishable from that of trigeminal neuralgia. Treatment options include carbamazepine, baclofen, and tricyclic antidepressants. Fatigue, which is common, may be ameliorated with amantadine. This agent produces partial relief for a minority of patients. In controlled studies, the effect is only slightly better than placebo.

Disposition

Patients with a history of MS who seek treatment for significant symptoms must first be evaluated to rule out other, non-MS-related pathology. Also, the presence of other systemic illnesses, especially infections, which can worsen the symptoms of MS, should be excluded. If the problem is thought to be an exacerbation of MS, most patients will require hospital admission for intravenous steroid therapy. An alternative to hospitalization may be to initiate intravenous steroids in the ED and to arrange for a next-day follow-up visit with the primary care physician or neurologist if outpatient intravenous steroid administration is an option.

Patients with the new onset of symptoms suggestive of MS should be admitted or referred to a neurologist, depending on the type and severity of symptoms.

---

**KEY CONCEPTS**

- Any patient with a long-term illness, such as MS, must be evaluated to rule out pathologic processes not related to that illness before an exacerbation of the illness can be assumed to be the cause of any problems experienced by the patient.
- Therapy for patients with MS will require consultation with the patient’s primary care provider or neurologist to provide consistent disease management.
- Intravenous methylprednisolone effectively promotes earlier resolution of recurrences.
- Intravenous methylprednisolone has been shown to speed the recovery from vision loss from optic neuritis.

This chapter discusses cranial nerve problems, cerebral venous thrombosis, and multiple sclerosis—neurologic disorders that often provide significant diagnostic and therapeutic challenges in management in the emergency department (ED) setting (Table 103-1).

TRIGEMINAL NEURALGIA

Perspective

Trigeminal neuralgia, or tic douloureux, is a syndrome featuring painful paroxysms in one or more distributions of the trigeminal nerve. Trigeminal neuralgia is relatively uncommon, with an annual incidence of 4 to 13 cases per 100,000 population.1,2 It is more common in women than in men, with a female-to-male ratio of 1.7:1. Affected persons typically are between 50 and 69 years of age, and symptoms occur more frequently on the right side of the face.3

Pathophysiology

Trigeminal neuralgia is an idiopathic disorder, although significant evidence points to vascular compression of the trigeminal nerve root in many cases. This compression commonly is caused by a tortuous arterial or venous loop in the posterior fossa, an arteriovenous malformation, or rarely a tumor. In surgical case series, vascular compression of the trigeminal nerve root is found in 80 to 90% of cases.4,5 Of note, however, structural lesions are not found in all patients with trigeminal neuralgia.6

Clinical Features

Trigeminal neuralgia manifests with unilateral facial pain, typically characterized as lancinating paroxysms of pain in the lips, teeth, gums, or chin. The pain of trigeminal neuralgia commonly is associated with physical triggers such as chewing, brushing the teeth, shaving, washing or touching the affected area of the face, swallowing, or exposure to hot or cold temperature in the affected area. The maxillary and mandibular divisions of the trigeminal nerve are most commonly involved; rarely, the ophthalmic division alone is involved. Patients tend to experience the pain in clustered episodes that last a few seconds to several minutes. The attacks can occur during the day or night but rarely arise during sleep.6,7

Diagnostic Strategies

A careful history and physical examination should be performed to rule out other painful facial conditions including odontogenic infections, sinus disease, otitis media, acute glaucoma, temporomandibular joint disease, and herpes zoster. Patients who lack local pathologic findings to explain the painful syndrome require a very careful neurologic examination. The presence of a neurologic deficit should prompt suspicion of a structural lesion, such as aneurysm, tumor, or other intracranial lesion such as from multiple sclerosis (MS). Of note, 2 to 4% of patients with trigeminal neuralgia also have MS.8 Patients with normal findings on the head and neck examination and no neurologic deficits who have episodic, unilateral facial pain associated with nonpainful triggers are likely to have trigeminal neuralgia.

Management

Since the 1960s the medical treatment of choice for trigeminal neuralgia has been use of the anticonvulsant carbamazepine. The purported effectiveness of this treatment is, however, based on uncontrolled studies, and the mechanism of action of anticonvulsant therapy for trigeminal neuralgia is unclear. The true efficacy of medical therapy is difficult to assess owing to a very high rate of spontaneous remission. Nonetheless, carbamazepine appears to be an effective and well-tolerated agent for treatment of trigeminal neuralgia. The initial dosage of carbamazepine is 100 mg twice daily; this dose is then increased to three times daily after one week. The dose may be increased by 100 mg per day, up to a maximum of 1200 mg per day. A complete blood count and liver function studies should be performed periodically in these patients to monitor for hematologic and hepatic side effects. Additional agents that have been used for treatment of trigeminal neuralgia include phenytoin, baclofen, valproate sodium, lamotrigine, and gabapentin. None of these drugs have been shown to be more effective than carbamazepine.7

Surgical management has been a therapeutic option since the 1950s. Surgical procedures include both peripheral approaches and central procedures. Peripheral strategies include medication injection and cryotherapy techniques designed to temporarily block, or permanently ablate, branches of the peripheral trigeminal nerve. Although these procedures are relatively effective initially, recurrence is common. Repeated nerve

Tumor: Orbital compressive lesion  
Inflammatory: Optic neuritis (MS)  
Ischemic: Ischemic optic neuropathy |
| Cranial nerve III: Oculomotor nerve | Extraocular motor function via motor fibers to levator palpabre, superior rectus, medial rectus, inferior rectus, inferior oblique muscles  
Pupillary constriction via parasympathetic fibers to constrictor pupillae and ciliary muscles | Ptosis caused by loss of levator palpabre function  
Eye deviated laterally and down  
Diplopia  
Dilated, nonreactive pupil  
Loss of accommodation | Trauma: Herniation of the temporal lobe through the tentorial opening causing compression and stretch injury to the nerve  
Ischemic: Especially in diabetes  
Microvascular ischemic injury to nerve causes extraocular muscle paralysis but usually is papillary-sparing (often painful)  
Vascular: Intracranial aneurysms may press on the nerve, leading to dysfunction  
Myasthenia gravis can lead to atraumatic ocular muscle palsy |
| Cranial nerve IV: Trochlear nerve | Motor supply to the superior oblique muscle | Inability to move eye downward and laterally  
Diplopia  
Patients tilt head toward unaffected eye to overcome inward rotation of affected eye | Trauma is the most common cause of nerve dysfunction |
| Cranial nerve V: Trigeminal nerve | Motor supply to muscles of mastication and to tensor tympani  
Sensory to face, scalp, oral cavity (including tongue and teeth) | Partial facial anesthesia  
Episodic, lancinating facial pain associated with benign triggers such as chewing, brushing teeth, light touch | Trauma:  
Facial bone fracture may injure one section, leading to area of facial anesthesia  
Tic douloureux  
Tumor: Lesions in the cerebellopontine angle  
Any lesion, vascular or otherwise, in the cavernous sinus may compress nerve |
| Cranial nerve VI: Abducens nerve | Motor supply to the lateral rectus muscle | Inability to move affected eye laterally  
Diplopia on attempting lateral gaze | Trauma:  
Facial bone fracture may injure one section, leading to area of facial anesthesia  
Tic douloureux  
Tumor: Lesions in the cerebellopontine angle  
Any lesion, vascular or otherwise, in the cavernous sinus may compress nerve  
Elevated intracranial pressure (ICP): Because of its position and long intracranial length, increased ICP from any cause may lead to injury and dysfunction of the nerve |
| Cranial nerve VII: Facial nerve | Motor supply to muscles of facial expression  
Parasympathetic stimulation of the lacrimal, submandibular, and sublingual glands  
Sensation to the ear canal and tympanic membrane | Hemifacial paresis:  
Lower motor neuron lesion leaves entire side of face paralyzed  
Upper motor neuron lesion leaves forehead musculature functioning  
Abnormal taste  
Sensory deficit around ear  
Intolerance to sudden loud noises  
Unilateral hearing loss  
Tinnitus  
Vertigo, unsteadiness | Lower motor neuron:  
Infection (viral): The likely cause of Bell’s palsy  
Lyme disease: The most common cause of bilateral cranial nerve VII palsy in areas where Lyme disease is endemic  
Bacterial infection extending from otitis media  
Upper motor neuron: Stroke, tumor  
Tumors: Acoustic neuroma  
Mimics Ménière’s disease, perilymphatic fistula |
| Cranial nerve VIII: Vestibulocochlear nerve | Hearing and balance | | |
blocks are not recommended owing to a high risk of permanent facial anesthesia.

Central procedures can be divided into percutaneous approaches and open approaches. Percutaneous destruction of the trigeminal ganglion can be done by means of radiofrequency ablation, thermal ablation, glycerol injection, or balloon microcompression. These procedures carry the risk of corneal anesthesia, oculomotor paresis, or masticatory weakness.9

Open surgical management is the surgical option of choice in most treatment centers. Open surgical procedures include microvascular decompression of the nerve with or without partial ablation. Although the open microvascular decompression procedure has proved to be very effective, with pain relief achieved in 80 to 95% of patients, the surgery is associated with the risk of significant complications, including hearing loss, facial anesthesia, cerebrospinal fluid leak, brainstem or cerebellar injury, headaches, meningitis, and death.10,11 Gamma knife radiosurgery, a minimally invasive, precision-directed stereotactic radiosurgery, also has been associated with good outcomes. This highly specialized technique requires extremely sophisticated stereotactic radiofrequency equipment and is available only in specialized centers.12,13

**Disposition**

Patients with suspected trigeminal neuralgia should be referred for specialty evaluation. Patients with a neurologic deficit require urgent imaging studies, typically magnetic resonance imaging (MRI), to rule out a mass or vascular abnormality.

---

**KEY CONCEPTS**

- Patients with unilateral, intermittent, lancinating facial pain without abnormalities on physical examination are likely to have trigeminal neuralgia.
- Carbamazepine is the first-line agent for medical treatment.
- Patients who do not tolerate or whose pain is refractory to medical management may be candidates for microvascular decompression or ablation.

---

**FACIAL NERVE PARALYSIS**

**Perspective**

The acute onset of facial nerve paralysis often will prompt an ED visit, when early diagnosis and therapy can improve the patient’s chance for recovery of function of the facial nerve. Facial nerve paralysis of acute onset affects approximately 20 to 25 persons per 100,000 population per year, without geographic, gender, or race predilection.14,15

**Principles of Disease**

The facial nerve innervates the muscles of facial expression and the muscles of the scalp and external ear, in addition to the buccinator, platysma, stapedius, stylohyoid, and posterior belly of the digastric muscles. The sensory portion of the nerve supplies the anterior two thirds of the tongue with taste and
Pathophysiology

Although a complete list of possibilities in the differential diagnosis for facial nerve paralysis would be a long one, the causes pertinent to emergency medicine can be grouped into three specific categories: infectious, traumatic, and neoplastic.

Infection

Bell’s Palsy

Bell’s palsy, also commonly called idiopathic facial paralysis, has long been postulated to have a viral cause. This disease entity is characterized by an abrupt onset of a lower motor neuron paresis that can progress over 1 to 7 days to complete paralysis. A prodromal illness is described by 60% of patients. Symptoms and signs frequently associated with the facial paresis include ear pain, a perception of sensory change on the involved side of the face, decreased tearing, an overflow of tears on the cheek (epiphora), abnormally acute hearing (hyperacusis), and an impairment or perversion of taste (dysgeusia).18

Treatment approaches can be medical or surgical. The primary medical therapies for Bell’s palsy center on reducing inflammatory changes to the nerve with corticosteroids and treating the presumed viral cause. If these therapies are unsuccessful then surgical decompression may be considered.

The use of corticosteroids for Bell’s palsy has been controversial. The rationale for this application of steroid therapy is that edema of the nerve, confined within the facial canal, is thought to cause or contribute to the nerve injury. On the basis of this theory, most experts currently recommend a course of prednisone with an initial dose of 1 mg/kg per day for 7 to 10 days, with or without a short taper.14,17,19,20 The most definitive randomized, double-blind, placebo-controlled trial involving 496 patients showed an improvement in complete recovery of facial nerve function at 3 months from 64% with placebo to 83% with the use of prednisolone in a dose of 25 mg by mouth twice daily.21 Therapy should be started as soon as possible, ideally within the first 24 hours, but is still recommended for patients without contraindications who seek treatment within 1 week of symptom onset.19

A number of publications have advanced the belief that Bell’s palsy may be caused by herpesvirus infection. One study demonstrated herpes simplex virus type 1 DNA in the endoneurial tissue of 11 of 14 patients with Bell’s palsy but not in that of control subjects.22 In a trial of prednisone and acyclovir in 99 patients, patients treated with prednisone and acyclovir had a more favorable recovery than that observed in patients receiving prednisone alone.23 A study of 296 patients with Bell’s palsy treated with valacyclovir or placebo in addition to a fixed dose of prednisolone found significant benefit to the addition of valacyclovir, particularly in the setting of severe palsy or in those treated within 24 hours of symptom onset.24 Other studies have found conflicting results. Despite a lack of overwhelming evidence, the addition of an antiviral agent should be considered in the treatment of Bell’s palsy, especially with severe loss of function. The most commonly recommended antiviral regimens include valacyclovir, 1000 mg orally two times daily for 10 days. Valacyclovir and famciclovir have better oral absorption, are better tolerated, and are dosed less frequently, resulting in higher compliance. Accordingly, they have been recommended as alternatives to acyclovir.17,19,20,22,25 As with steroid therapy, although earlier treatment is preferred, treatment should be considered for patients presenting within 1 week of symptom onset.

Ramsay Hunt Syndrome

Ramsay Hunt syndrome (herpes zoster oticus) is characterized by unilateral facial paralysis, a herpetiform vesicular eruption, and vestibulocochlear dysfunction. The vesicular eruption may occur on the pinna, external auditory canal, tympanic membrane, soft palate, oral cavity, face, and neck as far down as the shoulder. The pain is considerably more severe than that associated with Bell’s palsy, and it frequently is out of proportion to physical findings. In addition, outcomes are worse than with Bell’s palsy, with a lower incidence of complete facial recovery and the possibility of sensorineural hearing loss. Therapy is similar to that for Bell’s palsy. Both prednisone and antiviral therapy for 7 to 10 days are advocated.17,26,27

Lyme Disease

Lyme disease is the most frequent vector-borne infection in the United States. It is caused by the spirochete Borellia burgdorferi and is spread by the bite of Ixodes genus ticks. Neurologic manifestations can arise in any phase of the disease, and the incidence of facial palsy in patients with neurologic involvement is 35 to 51%. In regions in which Lyme disease is endemic, it has been shown to be the leading cause of facial paralysis in children, responsible for one half of all pediatric cases of facial nerve paralysis.28,29

Bilateral facial nerve paralysis is rare but can occur with systemic infections. The two diseases most commonly associated with bilateral simultaneous onset of facial paralysis are Lyme disease and infectious mononucleosis. Bilateral facial paralysis should be considered to be a manifestation of Lyme disease until further testing excludes this diagnosis.20,28-30 The evaluation and treatment of Lyme disease are discussed in Chapter 132.

Bacterial Infections

Facial paralysis can be caused by acute bacterial infections of the middle ear, mastoid, or external auditory canal. In the preantibiotic era, facial paralysis was associated with acute otitis media in approximately 2% of cases; today, however, it occurs in only 0.2% of cases. Treatment consists of intravenous antibiotics and myringotomy for decompression. Malignant otitis externa can be associated with facial paralysis. This disease entity is most commonly seen in immunocompromised patients and usually is caused by Pseudomonas infection. Treatment involves prolonged intravenous anti-pseudomonal antibiotic therapy and may require surgical débridement.20,31

Trauma

In patients with head trauma, the facial nerve is the most commonly injured cranial nerve. The cause generally is a temporal bone fracture with nerve transection. Surgical exploration is warranted if there is firm evidence that the nerve has been transected, indicated by a sudden onset of complete unilateral facial paralysis, loss of electrical activity, and evidence of a displaced fracture involving the facial canal.
Neoplasm

Tumors of the facial nerve itself, or tumors anywhere along the course of the facial nerve that invade or compress the nerve, may lead to facial paralysis. Typically the course is progressive over at least 3 weeks. A sudden onset of paralysis, however, does not rule out an underlying tumor, because facial paralysis secondary to a neoplasm is of sudden onset in approximately 25% of cases.32 A neoplastic cause should be suspected in patients who suffer from recurrent ipsilateral facial paralysis, significant pain, prolonged symptoms, or any other concomitant cranial nerve abnormality.

Clinical Features and Differential Considerations

The medical history should focus on onset of the paralysis, concentrating on timing and rapidity of onset and looking for any associated signs and symptoms. A rapid onset of facial paralysis with dysgeusia and hyperacusis preceded by a viral prodrome is suggestive of Bell’s palsy. A history of recurrent ipsilateral paralysis or slow progression of symptoms is more characteristic for a tumor. Associated cranial nerve abnormalities, although occasionally seen with Bell’s palsy, also point to the possibility of a tumor or ischemic insult. The Ramsay Hunt syndrome causes significant pain and a vesicular rash, although the rash may follow the facial paresis by a few days. Significant anatomic abnormalities on visual or otoscopic inspection of the ipsilateral ear will be found with bacterial otitis media and otitis externa. Finally, systemic symptoms or bilateral facial paresis, especially in endemic areas, should raise the possibility of Lyme disease.

Diagnostic Strategies

The diagnostic workup of acute facial nerve paresis is based on whether the clinical picture is suggestive of a disease process other than Bell’s palsy. If the clinical history is classic for Bell’s palsy, then no imaging or laboratory studies are required. Of note, any history of possible exposure warrants serologic evaluation for Lyme disease. Although outpatient testing including electroneurography may ultimately be performed, this usually is not part of the initial evaluation.

The physical examination finding of a “central” seventh nerve paralysis (upper face–sparing) should prompt imaging with computed tomography (CT) or MRI, and consideration should be given to the possibility of an acute stroke or other hemispheric lesion. History or physical examination findings suggestive of a possible tumor require imaging to rule out a neoplasm. The study of choice will depend on the institution and preferences of the consultant.

Disposition

The vast majority of patients who have a seventh nerve paralysis will have a clinical diagnosis of Bell’s palsy and may be discharged with referral for short-term follow-up. Patients with a possible hemispheric process such as stroke or tumor should be hospitalized for further evaluation. Patients suspected of having Lyme disease require immediate initiation of appropriate antibiotic therapy.

In patients with a peripheral facial nerve paralysis, the ipsilateral eye should be patched, and consideration should be given to ophthalmologic follow-up, because there is a high rate of corneal abrasions and corneal dryness associated with the inability to properly blink or completely close the eye.

KEY CONCEPTS

- Recent literature highlights significant potential benefit for patients with clinical evidence of Bell’s palsy when they are treated early in the course with corticosteroids.
- The additional benefit of adding antiviral medication is controversial, but this treatment probably is warranted in patients with severe loss of function.
- Slowly progressive facial paralysis is suggestive of a neoplasm. Recurrent unilateral paralysis may occur with Bell’s palsy but frequently (30%) is seen in patients with tumor.
- Simultaneous bilateral facial paralysis is suggestive of Lyme disease, which must be considered as a possible cause, especially in endemic regions.
- Patients who have facial muscle paresis with intact forehead movement should be considered to have an upper motor neuron lesion until the diagnostic investigation proves otherwise.

VESTIBULAR SCHWANNOMA

Perspective

Vestibular schwannoma, formally referred to as acoustic neuroma, is a rare but important cause of sensorineural hearing loss. The annual incidence of VS is 1 case per 100,000 population, with a mean age at the time of detection of 46 to 58 years.33 The female-to-male ratio is 1.5:1. Vestibular schwannoma is very rarely bilateral, occurring in this form in approximately 5% of cases and generally associated with type II neurofibromatosis. Although histologically benign, vestibular schwannoma can cause neurologic damage by direct compression on the eighth cranial nerve and the other structures in the cerebellopontine angle.34

Principles of Disease

Vestibular schwannoma arises from the Schwann cells covering the vestibular branch of the eighth cranial nerve as it passes through the internal auditory canal. The tumor may compress the cochlear (acoustic) branch of the eighth cranial nerve, causing hearing loss, tinnitus, and dysequilibrium. Continued growth of the tumor may result in compression of structures in the cerebellopontine angle, where the facial and trigeminal nerves may be compressed and damaged. Larger tumors may further encroach upon the brainstem and if large enough may compress the fourth ventricle, ultimately resulting in signs of increased intracranial pressure (ICP).35

Clinical Features

Asymmetrical sensorineural hearing loss is the hallmark of vestibular schwannoma. Up to 15% of patients with this tumor, however, will have normal results on an audiogram. These patients typically have symptoms such as unilateral tinnitus, imbalance, headache, fullness in the ear, otalgia, or facial nerve weakness. Thus, patients with asymmetrical symptoms should be further evaluated for vestibular schwannoma even with normal findings on the audiogram.36

Vestibular schwannomas are extremely slow-growing tumors, averaging an approximately 1-mm increase per year, although many do not grow at all on serial examinations.32 Symptom onset is therefore generally quite gradual. In one series of 126 cases, the average time from symptom onset to discovery of a vestibular schwannoma was approximately 4 years.38
When vestibular schwannoma is suspected, the patient should be evaluated with an audiogram or a gadolinium-enhanced MRI. This imaging technique is extremely sensitive and has led to earlier diagnosis and a decrease in mean size at detection of vestibular schwannoma. CT lacks the necessary sensitivity in the posterior cranial fossa to reliably rule out the presence of vestibular schwannoma. The smaller the tumor at the time of diagnosis, the more options there are for therapy and the better the potential prognosis.34

**Differential Considerations**

A majority of disease entities included in the differential diagnosis for acoustic neuroma cause symmetrical sensorineural hearing loss. Asymmetrical sensorineural hearing loss has few causes other than vestibular schwannoma. Ménière’s disease may present a diagnostic dilemma because it can be asymmetrical. Ménière’s disease may be differentiated from vestibular schwannoma in that the tinnitus of Ménière’s disease usually is intermittent, whereas the tinnitus of vestibular schwannoma typically is continuous. In addition, patients with Ménière’s disease typically describe vertigo, whereas patients with a vestibular schwannoma are more likely to describe imbalance or dysequilibrium.

Vestibular schwannomas account for 80% of all cerebellopontine angle tumors. Among all other lesions, meningioma is the most common. Meningiomas more frequently cause symptoms of facial palsy or trigeminal nerve abnormality. Of note, however, considerable similarity between the clinical picture of a meningioma and that of vestibular schwannoma in the cerebellopontine angle has been described.39

**Management**

Vestibular schwannoma may be removed surgically or ablated with stereotactic radiation. In general, tumors larger than 3 cm are recommended for microsurgery, because radiation treatments, such as with the Gamma Knife or linear accelerator, are less effective for local control and growth arrest in larger masses. Smaller tumors are amenable to use of stereotactic radiation, which may have greater salvage rates of facial nerve function and hearing. Stereotactic radiation therapy generally has good long-term outcomes of local growth arrest, with nerve salvage approaching 90% or greater. Injuries to the trigeminal, facial, and acoustic nerves, and to the cerebellum, are possible complications of both procedures. In patients who are minimally symptomatic with small tumors, serial monitoring with MRI is a viable nonsurgical option. All patients should be evaluated by a specialist in the evaluation and treatment of vestibular schwannoma, because smaller tumor size at detection is associated with a better long-term outcome.35,37

**Disposition**

Patients with suspected acoustic neuroma should be referred for an audiogram or MRI and evaluation by a specialist in either otolaryngology or neurosurgery.

**DIABETIC CRANIAL MONONEUROPATHY**

**Perspective**

Cranial mononeuropathies occur uncommonly, usually are a complication of diabetes, and most often affect the extraocular muscles. The oculomotor nerve is most commonly affected, followed in order by the trochlear and abducens nerves. In one large series in Japan, the incidence of cranial nerve palsies was 1.0% among diabetics and 0.1% among nondiabetics.40,41 Whereas ophthalmoplegia appears to be closely related to diabetes, facial palsy is less strongly correlated with this disease.40

**Principles of Disease**

The pathologic basis of diabetic mononeuropathy appears to be ischemia of the affected cranial nerve caused by occlusion of an intraneural nutrient artery serving the nerve. This occlusion leads to injury located primarily in the center of the nerve, because the core fibers are more dependent on the supply from such nutrient arteries. The peripheral fibers are less affected because they also are supplied by collateral vessels. In the oculomotor nerve, the preservation of the circumservically located parasympathetic fibers explains the pupillary sparing that usually is found in this syndrome. In two studies, the microvascular changes in the intraneuronal arteries that lead to occlusion were noted in diabetic patients but absent in nondiabetics.32,43

**Clinical Features**

Patients typically describe acute onset of unilateral retro-ocular pain, diplopia, and ptosis.41 The physical manifestations of a third cranial nerve palsy include the inability to move the eye superiorly and medially, accompanied by ptosis. The pupillary light reflex usually is present. Although a less common finding, the fourth and sixth cranial nerves may be affected. Patients with a fourth cranial nerve palsy are unable to move the eye inferolaterally, and those with a sixth cranial nerve palsy are unable to move the eye laterally. Because of the long intracranial course of the sixth nerve, a patient with an isolated sixth nerve palsy should be evaluated for an intracranial lesion or increased ICP.34

**Differential Considerations**

Evaluating cranial nerve dysfunction requires a thorough history and physical examination and cranial imaging, usually with MRI. Diabetic mononeuropathy should be considered a diagnosis of exclusion, with considerations in the differential diagnosis including trauma, tumor, vertebrobasilar ischemia, aneurysm, and hemorrhage into the brainstem.45

**Management**

Treatment consists of patching the affected eye and administration of analgesics and antiplatelet therapy. The prognosis is good. If the neuropathy does not begin to resolve within 3 to 6 months, or if more than one nerve is affected, another cause should be sought. Complete resolution is expected within the first year. Antioxidant preparations, including α-lipoic acid, have been used therapeutically and have not shown harm, but
such agents have yet to be shown to have convincing clinical effect.\textsuperscript{46}

\begin{table}[h]
\centering
\begin{tabular}{|l|}
\hline
\textbf{Key Concepts} \\
\hline
- Diabetic neuropathy is a diagnosis of exclusion because no definitive diagnostic testing is available. \\
- Both ischemic and hemorrhagic brainstem lesions must be ruled out in the case of an acute ophthalmoplegia. \\
- Extraocular mononeuropathy is sufficiently common in patients with diabetes mellitus that its occurrence in isolation warrants evaluation of the patient for previously undiagnosed diabetes. \\
\hline
\end{tabular}
\end{table}

\section{Cerebral Venous Thrombosis}

\subsection{Perspective}

No precise studies of the epidemiology of cerebral venous thrombosis (CVT) have been performed. In case series, the median patient age is approximately 37 years, with a female-to-male ratio of 3:1.\textsuperscript{47}

\subsection{Principles of Disease}

Cerebral blood is drained by several major veins that lead into the dural sinuses. The major dural sinuses are the superior sagittal sinus, the inferior sagittal sinus, the straight sinus, the lateral sinuses, and the sigmoid sinuses. The variability in symptoms and signs in patients who present with CVT stems from differences in thrombus location and acuity of thrombus formation. Symptoms of intracranial hypertension are present in most patients with sinus thrombosis, whereas those with thrombosis of the cerebral veins are thought to be more prone to hemorrhagic infarction and localizing neurologic deficits.\textsuperscript{48} As with venous thrombosis in other locations, multiple causes and predisposing factors for CVT are recognized. Underlying causes often are divided into infectious and noninfectious categories. Infectious causes include local infections, such as sinusitis, otitis media, cellulitis on the face, and systemic infections. Noninfectious causes include direct injury to the cerebral venous system from trauma, surgery, tumor, dehydrenation, or any other condition that may predispose the patient to development of a hypercoagulable state.\textsuperscript{49}

\subsection{Clinical Features}

The symptoms and signs associated with CVT are quite varied. Headache is the primary feature of CVT in 74 to 92\% of affected patients.\textsuperscript{49,50} Papilledema is noted in 28 to 45\% of cases.\textsuperscript{49,50,51} Lethargy, decreased level of consciousness, or mental status changes may be noted. Seizures occur in 35 to 50\% of patients in the acute phase.\textsuperscript{47,49,51} In addition to the location and acuity of thrombosis formation, a patient’s symptom onset will vary in accordance with the extent of collateral vessel growth in the venous territory. Early thrombotic changes may be well compensated for by the collateral venous drainage. Symptoms will appear only when the compensation for venous thrombosis is no longer sufficient. Variability in collateralization between patients also adds to the variability and time course of symptomatology. Two national and international observational studies document an average time from symptom onset to diagnosis of 7 days, reflecting the difficulty in diagnosing this rare disease entity.\textsuperscript{47,51,52} The reported incidence of focal neurologic signs, including seizures, on clinical examination varies between series, ranging from 25 to 71\%.\textsuperscript{49,50} Because of the broad spectrum of possible clinical features, the diagnosis of CVT may be difficult but should be a consideration in any patient with unexplained headache, especially in combination with focal neurologic deficit, papilledema, or seizures.

\subsection{Diagnostic Strategies}

The gold standard modality for the diagnosis of CVT has shifted in recent years from cerebral angiography to magnetic resonance venography (MRV). CT scanning is useful in the initial workup of the patient with possible CVT, but noncontrast CT is neither sensitive nor specific enough to reliably confirm or exclude the diagnosis. Findings on CT that are consistent with CVT include hyperdensity of a thrombosed sinus, brain edema, and hemorrhage secondary to venous congestion. CT venography is both more sensitive and more specific in diagnosing CVT.

Similar to CT scanning, MRI also can demonstrate local changes secondary to venous congestion, such as brain edema or hemorrhage. In addition, MRI can demonstrate the possibility of CVT based on the lack of a “flow void.” On conventional MRI, a flow void indicates the presence of blood flow within the sinus, whereas the absence of a flow void indicates a possible thrombus. Diagnostic accuracy, however, is greatly improved through use of MRV. This technique takes advantage of the MRI signal characteristics of flowing blood to create images of venous structures. Combining these imaging techniques further enhances diagnostic accuracy. For imaging a particular dural sinus, presence of the sinus on conventional MRI and lack of flow on MRV are diagnostic of a sinus thrombosis. This combined approach has diagnostic sensitivity similar to that of conventional angiography.\textsuperscript{49,53}

Two small studies show similar sensitivity between MRV and CT venography for the diagnosis of CVT when the CT study is performed on a multidetector row CT scanner. Both studies, involving a total of 69 patients, showed 100\% sensitivity of CT venography for CVT in comparison with MRV.\textsuperscript{54,55} The sensitivity of CT venography performed by scanners that do not use multidetector row technology is unknown.

Several small studies have attempted to evaluate the usefulness of the D-dimer assay as a screening tool to exclude CVT, particularly when MRI or CT venography is not available. Although the reported sensitivity rates are fair at 83 to 100\%, larger prospective studies need to be done to further define the role of D-dimer in the evaluation of CVT, because several case reports have noted normal D-dimer levels in the setting of documented CVT.\textsuperscript{56-59} In general, although a normal D-dimer level does not exclude the diagnosis of CVT, it does appear to make this diagnosis much less likely, particularly in a patient with symptoms of less than 2 weeks in duration.

\subsection{Differential Considerations}

Considerations in the differential diagnosis of CVT include the conditions that cause patients to present with the new onset of neurologic deficits, alteration in consciousness, or severe headache. A diagnosis of CVT should be considered in a patient with such symptoms when the etiology is unclear, presence of having a hypercoagulable state is likely, and the head CT scan is normal in appearance or shows subtle signs of CVT.

\subsection{Management}

CVT is a relatively rare disease, and controlled studies evaluating its treatment are lacking. Current therapeutic consensus
MULTIPLE SCLEROSIS

Perspective

Multiple sclerosis (MS) is an inflammatory disease that affects the central nervous system (CNS). Although the exact etiology remains uncertain, the pathologic manifestation of this inflammatory disease is a demyelination of discrete regions (plaques) within the CNS with a relative sparing of axons. The clinical picture is highly variable but is classically characterized by episodes of neurologic dysfunction that evolve over days and resolve over weeks.

MS has an overall prevalence in the United States of 0.1%. The peak age at onset is 25 to 30 years, with women being slightly younger at onset than men. The incidence in women exceeds that of men by a ratio of 1.8:1. The worldwide prevalence is greatest in the United Kingdom, Scandinavia, and North America. Epidemiologic studies indicate that both genetic and environmental factors are associated with an increased incidence of this disease. MS has a 30% concordance rate between monogygotic twins, and 20% of patients with MS have at least one affected relative. MS is more common in temperate climates. It is rare between 23 degrees north and south latitudes but has a rising incidence above and below 50 degrees north and south latitudes, respectively. Although no exact environmental factor has been identified, if a person emigrates from an area of high prevalence to an area of low prevalence before the age of 20, the risk is diminished. MS is rare in Africans and Asians, but African Americans have a higher incidence than their relatives who remain in Africa. In addition, reports of clusters or miniepidemics support environmental factors. Thus, an environmental cause superimposed on genetic susceptibility appears to be a likely etiologic scenario.

Principles of Disease

MS is considered to be an organ-specific autoimmune disease. One theory proposes that genetic factors interact with an environmental trigger or infection to establish pathologically autoreactive T cells in the CNS. After a long and variable latency period (typically 10 to 20 years), a systemic trigger, such as a viral infection or superantigen, activates these T cells. The activated T cells, on reexposure to the autoantigen, initiate the inflammatory response. This sets off a complex immunologic cascade that leads to the demyelination characteristic of MS. This demyelination process releases CNS antigens that are hypothesized to initiate further episodes of autoimmune-induced inflammation. The mechanisms underlying this autoimmunity in MS are unknown.

Clinical Features

The clinical picture in MS is one of marked heterogeneity. The classic clinical syndrome consists of recurring episodes of neurologic symptoms that rapidly evolve over days and slowly resolve. Variability occurs in age at onset, location of CNS lesions, frequency and severity of relapses, and the degree and time course of progression.

The clinical features of MS can be divided into areas of specific CNS impairment: cognition, cranial nerves, motor pathways, sensory pathways, cerebellar pathways, and bowel, bladder, and sexual dysfunction.

Patients with MS have frequent complaints of poor memory, distractibility, and a decreased capacity for sustained mental effort. Formal neuropsychological testing suggests that cognitive involvement is common and underreported. Specifically,
neuropsychological testing has shown that 43 to 65% of patients with MS have some degree of cognitive impairment.\textsuperscript{69,70} Of note, a correlation has been found between the MRI-based total lesion load and presence of cognitive impairment.\textsuperscript{71}

Cranial nerve dysfunction is common in MS. The most common associated cranial nerve abnormality is optic neuritis, a unilateral syndrome characterized by pain in the eye and a variable degree of visual loss affecting primarily central vision. Within 2 years of an attack of optic neuritis, the risk of MS is approximately 20%, and within 15 years, it is approximately 45 to 80%.\textsuperscript{72,73} Optic neuritis often is the first symptom of MS.\textsuperscript{74,75}

As a result of lesions in the vestibulo-ocular connections, the oculomotor pathways also may be affected. The deficit may manifest as diplopia or nystagmus. The nystagmus may be severe enough that the patient may complain of oscillopsia (a subjective oscillation of objects in the visual field). Cranial nerve impairment also may include impairment of facial sensation, which is relatively common. Unilateral facial paresis also may occur. In addition, the occurrence of trigeminal neuralgia in a young person may be an early sign of MS.

Motor pathways also are commonly involved. Specifically, corticospinal tract dysfunction is common in patients with MS. Paraparesis or paraplegia is all too common and occurs with greater frequency than upper extremity lesions, owing to the common occurrence of lesions in the motor tracts of the spinal cord. In patients with significant motor weakness, spasms of the legs and trunk may occur on attempts to stand from a seated position. This dysfunction is manifested on physical examination as spasticity that typically is worse in the legs than in the arms. The deep tendon reflexes are markedly exaggerated, and sustained clonus may be demonstrated. Although these symptoms frequently are bilateral, they generally are asymmetrical.\textsuperscript{76}

Sensory manifestations are a frequent initial feature of MS and will be present in nearly all patients at some point during the course of the disease. Sensory symptoms are commonly described as numbness, tingling, “pins and needles” paresthesias, coldness, or a sensation of swelling of the limbs or trunk.\textsuperscript{76}

Impairment of the cerebellar pathway results in significant gait imbalance, difficulty with coordinated actions, and dysarthria. Physical examination reveals the typical features of cerebellar dysfunction, including dysmetria, dysdiadochokinesis (an impairment of rapid alternating movements), a breakdown in the ability to perform complex movements, an intention tremor in the limbs and head, truncal ataxia, and dysarthria.\textsuperscript{76}

Impairment of bowel, bladder, and sexual function also is common. The extent of sphincter and sexual dysfunction usually parallels the motor impairment in the lower extremities. Urinary frequency may progress to urinary incontinence with progression of the disease. Anatomic bladder may develop, which empties by simple overflow and often is associated with the loss of perception of bladder fullness and with anal and genital hypesthesia. Constipation becomes common over time, and almost all patients with paraplegia require special measures to maintain effective bowel habits. Sexual dysfunction, although frequently overlooked, is very common in MS. Approximately 50% of patients become completely sexually inactive as a result of this disease.\textsuperscript{76}

**Diagnostic Strategies**

Although no laboratory tests are diagnostic for MS, one clinical feature remains relatively unique to this disease: Uhthoff’s phenomenon, temporary worsening of current or preexisting signs or symptoms of MS secondary to small increases in the patient’s body temperature. Accordingly, exercise, a hot bath, exposure to a warm environment, or fever can bring about Uhthoff’s phenomenon. This phenomenon reflects subclinical demyelination or preexisting injury to nerves without obvious significant clinical involvement before heat exposure or temperature elevation.\textsuperscript{66}

The clinical diagnosis rests on occurrence of at least two clinical episodes with different neurologic symptoms at different times. Thus, MS commonly has been characterized as a disorder with lesions that differ in time and space. It also has been described as a relapsing-remitting disorder with symptoms that fluctuate over time.

Findings on cerebrospinal fluid (CSF) analysis are abnormal in 90% of the cases. Fifty percent of patients will have pleocytosis, with more than 5 lymphocytes per high-power field in the CSF. Approximately 70% of patients will have an elevated gamma globulin level, with immunoglobulin G (IgG) ranging from 10 to 30% of the CSF total protein. Electrophoresis of the CSF demonstrates oligoclonal bands of IgG in 85 to 95% of patients who carry a diagnosis of MS; however, oligoclonal bands of IgG also are seen with neurosyphilis, fungal meningitis, and other CNS infections. Lumbar puncture should be considered for all patients with suspected MS, but mass lesions and elevated ICP should be ruled out before lumbar puncture.\textsuperscript{77}

The initial imaging test to aid in the diagnosis of multiple sclerosis is MRI. MRI is a sensitive test for the detection of lesions consistent with MS and also is useful to assess disease severity.\textsuperscript{78} The lesions of MS typically appear hyperintense, or bright white, on T2-weighted or fluid-attenuated inversion recovery (FLAIR) MRI studies. Lesions usually are multiple and commonly are found in the periventricular white matter.\textsuperscript{79}

In patients with an initial neurologic event consistent with CNS demyelination and an MRI cranial study showing multiple white matter lesions, the 5-year risk of developing MS is 60%. Patients with similar clinical syndromes and a normal MRI appearance have less than a 5% 5-year risk.\textsuperscript{80}

**Differential Considerations**

Other diseases that affect the CNS white matter may be clinically and radiographically similar to MS. Considerable care must be taken to exclude these disease processes before making a diagnosis. These include CNS tumors (especially lymphomas and gliomas), spinal cord compression, vasculitides, Behçet’s disease, neurosarcoidosis, postinfectious and postvaccinal encephalomyelitis, human immunodeficiency virus (HIV) encephalopathy, Lyme disease, and vitamin B12 deficiency.

**Management**

Management of patients with MS has essentially three aspects: (1) therapies aimed at halting the progression of the disease, (2) treatment for acute exacerbations, and (3) therapies designed to modify complications.

Therapies aimed at halting disease progress are based primarily on the use of either β-interferon or glatiramer acetate. The interferons are a group of natural compounds with antiviral and immunomodulatory actions, which are retained by the recombinant preparations used in therapy for MS, interferon beta-1a and interferon beta-1b. Side effects include flu-like symptoms, depression, anxiety, and confusion. In one study, 560 patients with MS were randomly assigned to receive subcutaneous interferon beta-1a or placebo (n = 187) three times a week for 2 years. The relapse rate was significantly lower at 1 and 2 years with interferon beta-1a than with placebo. The time to first relapse was prolonged significantly and the accu-
mulation of brain lesions on MRI was lower in the treatment group than in the placebo group. The investigators concluded that subcutaneous interferon beta-1a is a well-tolerated and effective treatment for relapsing-remitting MS in terms of relapse rate, defined disability, and all MRI outcome measures. β-interferon also has been shown to retard progression to clinically definite MS and to decrease the total number of brain lesions seen on subsequent MRI studies in patients who have their first demyelinating episode with MRI abnormalities at initial presentation. This finding highlights the importance of early evaluation and treatment.

Glatiramer acetate also has successfully been used in the treatment of MS. This agent is a mixture of synthetic polypeptides designed to mimic myelin basic protein. The mechanism of action by which glatiramer acetate exerts its effect is unknown, but it is thought to modify the immune processes responsible for the pathogenesis of MS. In one study, 251 patients with relapsing-remitting MS were randomized to receive daily subcutaneous injections of glatiramer acetate (previously called copolymer 1) or placebo for 24 months. Patients receiving glatiramer acetate experienced significantly fewer relapses and were more likely to demonstrate neurologic improvement, whereas those receiving placebo were more likely to worsen. This drug generally is quite well tolerated.

Current recommendations for management of relapsing-remitting MS are to initiate treatment with β-interferon or glatiramer acetate. Such regimens have been demonstrated to decrease the volume of plaques seen on MRI and to diminish relapses. Immunosuppressive agents, including mitoxantrone and azathioprine, also have been shown to be effective in reducing progression of disease but, in view of concerns over side effects, generally are used as second-line agents.

Acute exacerbations of MS also should be targets for therapy. Although most such episodes will resolve without therapy, steroids have been demonstrated to diminish the duration of acute exacerbations. More than 85% of patients with relapsing-remitting MS show improvement with intravenous methylprednisolone. Intravenous steroids have been shown in controlled trials to speed the recovery from the visual loss of optic neuritis when compared with placebo. In addition, when patients with acute optic neuritis are treated with high-dose intravenous steroids, the 2-year rate of development of MS is reduced, although this effect diminishes over time. Of interest, oral prednisone was not found to be helpful in the optic neuritis trials and was associated with a potential increase in the number of optic neuritis episodes.

The current standard therapy for an acute exacerbation in MS is intravenous methylprednisolone. A typical dose administered intravenously is 250 to 500 mg every 12 hours for 3 to 7 days. Whether this should be followed by an oral prednisolone taper remains controversial. Potential adverse effects of methylprednisolone therapy include fluid retention, gastrointestinal hemorrhage, anxiety, psychosis, infection, and osteoporosis.

Several therapies directed toward the complications of MS may be helpful. The associated spasticity generally is treated with baclofen. This is a highly effective therapy aimed at reducing the painful flexor and extensor spasms. A major side effect is drowsiness, which generally diminishes with continued use. Higher-dose therapy can cause confusion, especially in the setting of baseline cognitive impairment. For patients with intractable spasticity, baclofen is available for intrathecal administration by either bolus therapy or continuous implanted pump therapy. Additional therapeutic agents for control of spasticity include tizanidine, diazepam, and dantrolene.

The tremor and ataxia associated with MS occasionally are treated with propranolol, diazepam, or clonazepam. The results of these therapies, however, generally are unsatisfactory. Pain often is associated with MS and affects the shoulders, pelvic girdle, and face. The facial pain may be indistinguishable from that of trigeminal neuralgia. Treatment options include carbamazepine, baclofen, and tricyclic antidepressants. Fatigue, which is common, may be ameliorated with amantadine. This agent produces partial relief for a minority of patients. In controlled studies, the effect is only slightly better than placebo.

Disposition

Patients with a history of MS who seek treatment for significant symptoms must first be evaluated to rule out other, non-MS-related pathology. Also, the presence of other systemic illnesses, especially infections, which can worsen the symptoms of MS, should be excluded. If the problem is thought to be an exacerbation of MS, most patients will require hospital admission for intravenous steroid therapy. An alternative to hospitalization may be to initiate intravenous steroids in the ED and to arrange for a next-day follow-up visit with the primary care physician or neurologist if outpatient intravenous steroid administration is an option.

Patients with the new onset of symptoms suggestive of MS should be admitted or referred to a neurologist, depending on the type and severity of symptoms.

**KEY CONCEPTS**

- Any patient with a long-term illness, such as MS, must be evaluated to rule out pathologic processes not related to that illness before an exacerbation of the illness can be assumed to be the cause of any problems experienced by the patient.
- Therapy for patients with MS will require consultation with the patient’s primary care provider or neurologist to provide consistent disease management.
- Intravenous methylprednisolone effectively promotes earlier resolution of recurrences.
- Intravenous methylprednisolone has been shown to speed the recovery from vision loss from optic neuritis.

Spinal Cord Disorders

Andrew D. Perron and J. Stephen Huff

**PERSPECTIVE**

Spinal cord disorders encompass a wide range of pathologic entities and affect all age groups. Some spinal cord disorders may have catastrophic outcomes if not recognized early in the clinical course. The ultimate neurologic outcome with many of these disorders may depend on expeditious recognition in the emergency department (ED), with appropriate initial investigations, neuroimaging, management, and consultation for definitive therapy. Diagnosis of these disorders may be extremely challenging, and certain disorders may mimic other disease processes until late in the clinical course, when there is clear neurologic impairment. As with many disease processes affecting the nervous system, correct diagnosis and appropriate management require knowledge of the anatomic organization of the spinal cord and skill in taking the history and in performing the neurologic examination.

This chapter generally is concerned with processes affecting the spinal cord and its vascular supply, as well as processes compressing the spinal cord. Direct trauma and mechanical instability of the spinal column are discussed in Chapter 40.

**PRINCIPLES OF DISEASE**

**Anatomy**

In adults, the spinal cord is approximately 40 cm long and extends from the foramen magnum, where it is continuous with the medulla oblongata, to the body of the first or second lumbar vertebra. Similar to the brain, the spinal cord is covered by three meningeal layers: the inner pial layer, the arachnoid, and the outer dural layer. At its lower end, the spinal cord tapers into the conus medullaris, where several segmental levels are represented in a small area. The lumbar and sacral nerve roots form the cauda equina as they descend caudally in the thecal sac before exiting the spinal canal at the respective foramina. The non-neural filum terminale runs from the tip of the conus and inserts into the dura at the level of the second sacral vertebra.

Two symmetrical enlargements of the spinal cord contain the segments that innervate the limbs. The **cervical enlargement** (cord level C5 to T1) gives rise to the brachial plexus and subsequently to the peripheral nerves of the upper extremity. The **lumbar enlargement** (L2 to S3) gives rise to the lumbosacral plexus and peripheral nerves of the lower extremity. The space surrounding the spinal cord within the spinal canal is reduced in the area of the enlargements, potentially leaving the cord more vulnerable to compression in these regions. At each segmental level, anterior (ventral) and posterior (dorsal) roots arise from rootlets along the anterolateral and posterolateral surfaces of the cord. At each level, the anterior root conveys the outflow of the motor neurons in the anterior horn of the spinal cord, and the posterior root contains sensory neurons and fibers that convey sensory inflow.

The arterial supply of the spinal cord is derived primarily from two sources. The single anterior spinal artery arises from the paired vertebral arteries. This anterior spinal artery runs the entire length of the cord in the midline anterior median sulcus and supplies roughly the anterior two thirds of the spinal cord. Blood supply to the posterior third of the spinal cord derives from the smaller paired posterior spinal arteries. The anterior and the posterior spinal arteries receive segmental contributions from radicular arteries, the largest being the radicular artery of Adamkiewicz, which typically originates from the aorta between T8 and L4. The venous drainage of the cord largely parallels the arterial supply.

The internal anatomy of the spinal cord is divided into central gray matter, which contains cell bodies and their processes, and surrounding white matter, where the ascending and descending myelinated fiber tracts are located. These fiber tracts are organized into discrete bundles, with the ascending tracts conveying sensory information and the descending tracts conveying the efferent motor impulses and visceral innervation.

For clinical purposes, neuroanatomy of the spinal cord may be greatly simplified, as depicted in Figure 104-1. Major ascending sensory tracts are represented on the right side of the figure, with motor tracts on the left side. The posterior columns carry afferent ascending proprioceptive and vibratory information on the ipsilateral side of the cord to the area stimulated; decussation of these fibers occurs in the medulla so that contralateral cortical representation ultimately occurs. In a portion of the lateral column of white matter, the lateral spinthalamic tract conveys afferent information about pain and temperature. (Tracts are named with their point of origin first—the spinothalamic tract, for example, arises in the spinal cord and travels to the thalamus.) The tract is laminated so that sacral fibers are represented most laterally. Crossing of fibers from this tract occurs near the level of entry of the spinal nerve; a cord lesion affecting one lateral spinthalamic tract results in decreased or absent pain and temperature perception below the level of injury on the contralateral side of the body.
For clinical purposes, the major descending motor tract is represented in the lateral corticospinal tract (which, as the name implies, originates in the cortex and flows toward the spinal cord). This tract also is anatomically organized, with efferent motor axons to the cervical area located medially and the sacral efferent axons located laterally. Decussation of this descending tract occurs in the medulla. The cell bodies of the lower motor neurons (anterior horn cells) are in the ventral portion of the gray matter of the spinal cord.

### CLASSIFICATION OF SPINAL CORD SYNDROMES

The anatomic organization of the spinal cord lends itself to a corresponding anatomic-pathophysiologic classification of cord dysfunction. Any of the different anatomic syndromes may be the final clinical picture of a variety of clinical processes either intrinsic or extrinsic to the spinal cord. The syndromes frequently exist in partial or incomplete forms.

#### Complete (Transverse) Spinal Cord Syndrome

Complete spinal cord lesions may occur as either acute or subacute pathologic processes. A complete spinal cord lesion is defined as a total loss of sensory, autonomic, and voluntary motor innervation distal to the spinal cord level of injury. Reflex responses mediated at the spinal level, such as muscle stretch (“deep tendon”) reflexes, may persist, although they also may be absent or abnormal. Autonomic dysfunction may manifest with hypotension (neurogenic shock) or priapism. The most common cause of the complete transverse cord syndrome is trauma, although this anatomic syndrome is nonspecific as to etiology. Other causes of acute complete cord syndrome include infarction, hemorrhage, and entities causing extrinsic compression. Of patients in whom complete transverse syndromes develop and persist for more than 24 hours, functional recovery does not occur in 99%. Any evidence of cord function below the level of injury denotes a partial rather than a complete lesion. Signs such as persistent perineal sensation (“sacral sparing”), reflex rectal sphincter tone or voluntary rectal sphincter contraction, or even slight voluntary toe movement suggest a partial cord lesion, which usually carries a better prognosis than a complete lesion.

Spinal shock refers to the loss of muscle tone and reflexes with complete cord syndrome during the acute phase of injury. The intensity of the spinal shock increases with affected spinal cord level. Spinal shock typically lasts less than 24 hours but has been reported occasionally to last days to weeks. A marker of spinal shock is loss of the bulbocavernosus reflex, which is a normal cord-mediated reflex that also may be preserved in complete cord lesions. The bulbocavernosus reflex involves involuntary reflex contraction of the anal sphincter in response to a squeeze of the glans penis or a tug on the Foley catheter. The termination of the spinal shock phase of injury is heralded by the return of the bulbocavernosus reflex; increased muscle tone and hyper-reflexia follow later.

#### Incomplete Spinal Cord Lesions

Incomplete spinal lesions are characterized by preservation of function of various portions of the spinal cord. Of all incomplete spinal lesions, most can be classified generally as one of three clinical syndromes: central cord syndrome, Brown-Séquard syndrome, or anterior cord syndrome (Table 104-1).

#### Central Cord Syndrome

Central cord syndrome, first described by Schneider and colleagues in 1954, is the most prevalent of the partial cord syndromes. Because of the anatomic organization of the spinal cord, a central cord injury is characterized by bilateral motor paresis, with upper extremities affected to a greater degree than lower extremities, and distal muscle groups affected to a greater degree than proximal muscle groups. Sensory impairment and bladder dysfunction are variable features. At times, burning dysesthesias in the upper extremities may be the dominant feature. Central cord injury affects the central gray matter and the central portions of the corticospinal and spinothalamic tracts. It is caused most often by a hyperextension injury, with the postulated pathomechanism being squeezing or pinching of the spinal cord anteriorly and posteriorly by inward bulging of the ligamentum flavum. The most common cause of such injuries is a fall, followed in frequency by a motor vehicle crash. The result is contusion to the spinal cord, with the central portion being most affected. This injury classically occurs in elderly individuals with degenerative arthritis and spinal stenosis in the cervical area, but may affect any patient with cervical canal narrowing of any etiology (e.g., congenital narrow canal as seen in achondroplasia or canal narrowing from disk protrusion or tumor). The prognosis with central cord syndrome depends on the degree of injury at presentation and patient age. In patients younger than 50 years of age, more than 80% regain bladder continence, and approximately 90% return to ambulatory status. In patients older than 50, only 30% regain bladder function, with approximately 50% regaining the ability to ambulate.

#### Brown-Séquard Syndrome

Brown-Séquard syndrome, first described in 1846 by the one physician for whom it is named, is the result of an anatomic or functional hemisection of the spinal cord. Usually associated with penetrating injuries, Brown-Séquard syndrome also may be seen with compressive or intrinsic lesions. The syndrome has been reported in association with spinal cord tumors, spinal epidural hematoma, vascular malformations, cervical spondylosis, degenerative disk disease, and radiation injury and as a...

Complication of spinal instrumentation. The syndrome in its pure form is characterized by ipsilateral loss of motor function and proprioception or vibration, with contralateral loss of pain and temperature sensation, below the spinal cord level of injury. Because fibers associated with the lateral spinothalamic tract ascend or descend one or two spinal cord segments before crossing to the contralateral side, ipsilateral anesthesia (pain and temperature modalities) may be noted one or two segments above the lesion, although this observation is variable. Most patients with Brown-Séquard syndrome incur only partial sensory and motor impairment, and the classic pattern is not seen. Brown-Séquard syndrome carries the best prognosis of any of the incomplete spinal cord syndromes. Fully 80 to 90% of patients with Brown-Séquard syndrome regain bowel and bladder function, 75% regain ambulatory status, and 70% become independent in their activities of daily living.

Anterior Cord Syndrome

Anterior cord syndrome is characterized by loss of motor function, pinprick, and light touch below the level of the lesion, with preservation of posterior column function, including some touch, position, and vibratory sensation. Although most reported cases of anterior spinal syndrome follow aortic surgery, the syndrome also may occur after severe hypotension, infection, myocardial infarction, vasospasm from drug reaction, and aortic angiography. The anatomic lesion may be the result of a cervical hyperflexion injury resulting in a
cord contusion or from protrusion of bony fragments or herniated cervical disk material into the spinal canal. Rarely, it is produced by laceration or thrombosis of the anterior spinal artery or a major radicular feeding vessel. Patients present with the characteristic neurologic findings noted earlier. Functional recovery varies; most improvement occurs over the first 24 hours, but little improvement is expected thereafter. Although anterior cord lesions from ischemia usually are incomplete, patients without motor function at 30 days have little or no likelihood of regaining any motor function by 1 year. Overall, only 10 to 20% of patients with this entity regain some muscle function, and even in this group, there is little power or coordination.

Conus Medullaris Syndrome and Cauda Equina Syndromes

The separation of conus medullaris and cauda equina lesions in clinical practice is difficult because the clinical features of the disorders overlap. Additionally, a combined lesion may occur that masks clear clinical symptoms or signs of either an upper or a lower motor neuron type of injury. The conus medullaris is the terminal end of the spinal cord, located at approximately the L1 level in adults. The conus medullaris syndrome may involve disturbances of urination (usually from a denervated, autonomic bladder that manifests clinically with overflow incontinence) and sphincter impairment or sexual dysfunction. Sensory involvement may affect the sacral and coccygeal segments, resulting in saddle anesthesia. Pure lesions of the conus medullaris are rare. Upper motor neuron signs, such as increased motor tone and abnormal reflexes, may be present, but their absence does not exclude the syndrome. The conus medullaris syndrome can be caused by central disk herniation, neoplasm, trauma, or vascular insufficiency. Because the conus is such a small structure, with lumbar and sacral segments represented in a small area, a lesion usually causes bilateral symptoms. This finding may help distinguish lesions of the conus from lesions of the cauda equina, which often are unilateral.

The cauda equina (Latin for “horse’s tail”) is the name given to the lumbar and sacral nerve roots that continue on within the dural sac caudal to the conus medullaris. Not a true “cord syndrome,” cauda equina syndrome represents dysfunction at the level of nerve roots, but the anatomic clustering of nerve roots with the lumbar dural sac allows injury to several nerve roots to occur simultaneously. The etiologic lesion in the cauda equina syndrome usually is a midline rupture of an intervertebral disk, most commonly at the L4-5 level. Tumors and other compressive masses also may cause the syndrome. As in the conus medullaris syndrome, patients generally present with progressive symptoms of fecal or urinary incontinence, impotence, distal motor weakness, and sensory loss in a saddle distribution. Muscle stretch reflexes also may be reduced. The presence of urinary retention is the most consistent finding, with a sensitivity of 90%. Low back pain may or may not be present.

**CLINICAL FEATURES**

**History**

Weakness, sensory abnormalities, and autonomic dysfunction are the cardinal manifestations of spinal cord dysfunction. The tempo and degree of impairment often reflect the disease process. Past medical history is vital because a history of coagulopathy or other systemic processes may be elicited. A history of cancer should suggest the possibility of metastatic disease. Recent trauma raises the possibility of vertebral fracture or disk protrusion.

**Physical Examination**

The physical examination pertinent to spinal cord dysfunction involves testing in three areas: (1) motor function, (2) sensory function, and (3) reflexes. Each component is best tested with the anatomic organization of the spinal cord in mind to help determine the level of the spinal cord dysfunction.

**Motor Function**

Testing of motor function encompasses examination of muscle bulk, tone, and strength. Muscle bulk is easily examined in large motor groups, such as the thigh or calf muscles, the biceps, or the triceps. Inspection of the intrinsic hand muscles also may be helpful for determining muscle bulk; wasting may be evident as hollowed or recessed regions of the hand. Decreased mass, asymmetry, or fasciculations should be noted. Tone is tested with repeated passive knee, elbow, or wrist flexion, with the examiner feeling for abnormally increased or decreased resistance. Rapid pronation-supination of the forearm is another useful method to assess tone. Increased tone may indicate spasticity or an upper motor neuron lesion, whereas decreased tone corresponds with lower motor neuron, motor endplate, or muscular problems. Finally, motor strength is graded in the upper and the lower extremities. Motor grading for the neurologic examination is relatively straightforward. Scored on a scale of 0 to 5, neuromuscular functioning is graded as follows:

0: No firing of the muscle is present.
1: The muscle fires but is unable to move the intended part.
2: The muscle is able to move the intended part with gravity eliminated.
3: The muscle is able to move the intended part against gravity.
4: The muscle is able to move the intended part, but not at full strength.
5: Full muscular strength is present.

A rectal examination is performed to assess voluntary sphincter contraction, resting tone, and, as described previously, the bulbocavernous reflex.

**Sensory Function**

Sensory testing requires a cooperative patient and an attentive examiner. The spinal cord-related modalities that may be clinically useful in the ED setting include testing for pinprick, light touch (contralateral lateral spinothalamic tract), and proprioception (ipsilateral posterior column). Assessment of the patient’s response to pinprick, light touch, and proprioception in all four extremities is necessary if a neurologic injury is suspected. Testing of sacral dermatomes may be an important part of the examination in some patients. As previously noted, sacral sparing is an important finding indicating that spinal cord dysfunction may be incomplete. The sensory fibers from sacral dermatomes are more peripherally located in the ascending fiber bundles; central or partial cord lesions may ablate sensation in the extremities yet allow some perception of sensation in the sacral area.

**Reflexes**

Muscle stretch (“deep tendon”) reflexes may be tested rapidly at the bedside. Responses are graded on a scale of 0 to 4+, with...
2 being normal. Hyperactive reflexes suggest upper motor neuron disease (affecting the neurons or their outflow from the brain or spinal cord), as do sustained clonus and a Babinski’s sign. The absence of these reflex changes does not constitute evidence that a myelopathy is not present. In fact, one small series noted a low incidence of extensor planar responses, as well as a lack of hyper-reflexia, in patients presenting to the ED with acute or progressive cord compression or myelopathies. Reflexes also may be diminished or absent when sensation is lost, or when spinal shock is present, or when lower motor neuron disease is present. Diseases of muscles or neuromuscular junctions also may decrease reflexes. In acute cord injury, reflexes may be diminished in the acute phase. The bulbocavernous reflex may be helpful in this assessment.

### Diagnostic Strategies

Historical or physical examination findings that suggest spinal cord dysfunction prompt further investigations. The basic strategy is to detect or exclude extrinsic compressive lesions or other potentially treatable entities. Magnetic resonance imaging (MRI) has changed the diagnostic approach to patients with suspected spinal cord dysfunction. Plain radiographs and computed tomography (CT) scans may show bone and some soft tissue abnormalities. Conventional radiographs and CT scans are required in patients with trauma or suspected bone involvement by tumor or degenerative processes, but MRI shows many of these abnormalities and defines the spinal cord as well as the soft tissue structures associated with it. Tissue damage patterns within the cord, such as hemorrhage and edema, also may be detected with MRI. CT myelography may be able to answer some of these questions in patients in whom implanted metal precludes MRI but generally does not yield the same level of detail. After imaging studies exclude compressive lesions or other masses affecting the spinal cord, the possibility of inflammatory or demyelinating disorders remains, and lumbar puncture may be useful in diagnosis.

### Differential Considerations

The prime principle in management of spinal cord dysfunction is to consider and exclude potentially treatable problems. The clinical assessment of spinal cord dysfunction is limited to detecting weakness, sensory alterations, sphincter dysfunction, and perhaps reflex abnormalities. Pain in the back may be present depending on the pathologic process but generally is not helpful in formulating a list of considerations for the differential diagnosis. Because potential functional loss and impact on quality of life are great, the detection of a process for which some intervention is possible assumes great importance. A likely diagnosis of spinal cord infarction may be entertained, but the pursuit of a treatable process, such as spinal cord compression from an epidural hematoma, should be seriously considered. This discovery process may involve specialty consultation or obtaining studies not readily available in many ED settings, such as MRI. As a general rule, liberal use of consultation and imaging is recommended when the possibility of spinal cord dysfunction is considered. The history may suggest a specific cause and will guide the tempo of investigation. The caveat is that spinal cord diseases may mimic many other disease processes, and neither the history nor physical examination may allow diagnosis until appreciable neurologic dysfunction has developed.

The picture of a complete transverse spinal cord syndrome with paraplegia, sensory loss at a clear anatomic level, and sphincter dysfunction cannot be fully simulated by other anatomic lesions. Incomplete or evolving spinal cord syndromes may be imitated by other disease processes. It is always prudent to focus the differential diagnosis on anatomic considerations—the classic “where is the lesion?” approach (Table 104-2). Progressive lower extremity weakness and sensory alteration may represent cord dysfunction but could reflect an intracranial vertex mass with bilateral cortical dysfunction. Ataxia may be a finding in cerebellar disease but also has rarely been reported as an isolated finding with spinal cord compression. Another example is rapidly progressive paralysis in a patient with areflexia and quadriplegia; ascending paralysis (Landry-Guillain-Barré syndrome) at times may mimic an acute cord lesion.

Generally, pathologic processes involving the spinal cord may be divided into processes affecting the cord or its blood supply primarily, such as demyelination, infection, or infarction, and processes that compress the cord, most often originating outside the dura (Box 104-1). Myelitis is a comprehensive term for spinal cord inflammation with dysfunction, and the potential causes are legion. The clinical presentation often is similar across the variety of entities that may cause cord compression. The tempo of the process may yield a different clinical picture. In chronic compression, muscle wasting and abnormal reflexes may be present, whereas both of these may be lacking in acute compression. A neurologic deficit in concert with back pain strongly suggests a spinal cord lesion, necessitating prompt investigation to identify a specific cause. Atypical presentations for these lesions are the rule, and additional diagnostic studies should be pursued as appropriate.

MANAGEMENT

Just as the clinical manifestations of spinal cord dysfunction are nonspecific with respect to etiology, the treatment for many of the disease entities often is nonspecific. Steroid administration has been recommended as therapy in spinal cord trauma, although this use of steroids has been seriously questioned in the literature. Steroids also have been used with many nontraumatic causes of cord compression, despite the lack of rigorous clinical studies supporting this use. Radiation treatment is recommended for cord compression by tumor. Surgical consultation for decompression may be considered, although the indications for surgery and timing of surgery are controversial.

A specific diagnosis is needed to guide therapy. Accordingly, involvement of appropriate consultants and discussion of what may be understudied therapies are suggested.

SPECIFIC DISEASE PROCESSES

As noted earlier, spinal cord disorders may be grouped into lesions resulting from processes intrinsic to the cord and vasculature and lesions causing extrinsic compression. The order of the following discussion roughly corresponds with the organization of Box 104-1.

Intrinsic Cord Lesions

Multiple Sclerosis

Principles of Disease. Demyelination denotes a disease process with the prominent feature of partial or complete loss of the myelin surrounding the axons of the central nervous system. Multiple sclerosis (MS) is the most common example of such a process; spinal cord involvement may dominate the clinical picture.

Clinical Features. Central nervous system lesions that are “scattered in time and space” are the hallmark of MS. The demyelinated segments do not transmit action potentials normally, resulting in a wide variety of spinal cord–related abnormalities, depending on the location and extent of the demyelination.

In addition to patchy motor and sensory deficits, patients with MS may complain of bladder dysfunction or tremor or demonstrate evidence of a transverse partial or complete cord syndrome mimicking a compressive spinal lesion. The history may include a previous episode of optic neuritis or transient visual problems. Spinal cord lesions in MS primarily involve the lateral corticospinal tracts, the posterior columns, and the lateral spinothalamic tracts. Motor system dysfunction is the most frequent manifestation of MS involvement of the spinal cord, usually as a result of lesions in the lateral corticospinal tracts.

The examination of patients with MS often reveals paresis, increased muscle tone, hyper-reflexia, clonus, and a Babinski’s response. Spinal cord involvement also may result in dysautonomias.

Diagnostic Strategies. Spinal MRI is the diagnostic imaging modality of choice because it can exclude cord compression and show lesions suggesting MS. Cranial MRI may be helpful in showing other central nervous system lesions. Cerebrospinal fluid (CSF) testing for myelin basic protein and oligoclonal bands also is a diagnostic option, but no CSF abnormalities are entirely specific for MS. Oligoclonal bands in the CSF may aid in the diagnosis, but they are significant only if not present in the serum as well.

Differential Considerations. Considerations in the differential diagnosis include systemic lupus erythematosus, Lyme disease, neurosyphilis, human immunodeficiency virus (HIV) myelopathy, and other disorders.

Management. MS exacerbations may be treated with high-dose methylprednisolone followed by a tapering dose of prednisone. Corticosteroids have been shown to be useful in shortening the time required for recovery from an exacerbation of MS. Consultation and referral to a neurologist usually are indicated. Immunosuppressive therapy in patients with the chronic progressive form of the disease has met with variable success. Because numerous disorders can mimic MS, the definitive diagnosis of this disease usually is not made in the ED.

Transverse Myelitis

Principles of Disease. Acute transverse myelitis refers to acute or subacute spinal cord dysfunction characterized by paraplegia, a transverse level of sensory impairment, and sphincter disturbance. It is relatively rare, with a reported annual incidence of 1 case per 1.3 million population. The presentation may be mimicked by compressive lesions, trauma, infection, or malignant infiltration. The exact pathogenesis is unknown, although it is noted to follow viral infection in approximately 30% of patients and commonly is termed “postinfectious myelitis.” Other postulated etiologic categories include infectious, autoimmune, and idiopathic. No apparent cause for acute transverse myelitis is identified in 30% of the patients. Progression of symptoms usually is rapid, with 66% of the cases reaching maximal deficit by 24 hours. Symptoms may progress, however, over days to weeks. The thoracic cord region is affected most often by this process (60 to 70%); the cervical spinal cord is rarely affected.

Clinical Features. In addition to motor, sensory, and urinary disturbances, patients with acute transverse myelitis may complain of back pain and may have low-grade fever, raising concern for spinal epidural abscess. As with MS, the examination may reveal weakness progressing to paresis, hypertonia, hyper-reflexia, clonus, and a Babinski’s response. Spinal cord involvement also can result in dysautonomias.

Diagnostic Strategies. Evaluation for acute transverse myelitis is done primarily with emergent MRI to exclude compressive...
lesions. Results of CSF studies are normal in 40% of the cases, with only mildly elevated protein or pleocytosis in the remaining 60%. The most essential aspect of the evaluation is to eliminate a potentially treatable cause, such as spinal epidural abscess, neoplasm, or hematoma.

**Differential Considerations.** Considerations in the differential diagnosis for transverse myelitis include MS, spinal epidural abscess, spinal neoplasm, and hematoma.

**Management.** Treatment with steroids is of unknown benefit. Anecdotal reports of improvement after steroid administration exist, but some studies have found no benefit to their use. Neurologic consultation is suggested, and hospitalization usually is required.

The clinical course of acute transverse myelitis varies widely, ranging from complete recovery to death from progressive neurologic compromise. Maximal improvement usually is obtained within 3 to 6 months. At 5-year follow-up evaluation of one series of patients with this disease, 30% had a good recovery, 25% had a fair recovery, 30% had a poor outcome, and 15% had died as a result of complications of the disease.

**Spinal Subarachnoid Hemorrhage**

**Principles of Disease.** Intraspinal hemorrhage is rare and occurs in the same anatomic locations as intracranial hemorrhages: epidural, subdural, subarachnoid, and intramedullary hemorrhages are all possible. Spinal subarachnoid hemorrhage usually is caused by an arteriovenous malformation. Hemorrhage from tumors and cavernous angiomas and spontaneous hemorrhage secondary to anticoagulation therapy also have been reported. Bleeding may occur exclusively in the subarachnoid space or within the substance of the spinal cord itself.

**Clinical Features.** Patients present with excruciating back pain, of paroxysmal onset, at the level of the hemorrhage. This pain also may be in a radicular distribution or extend into the flank. Patients may complain of headache and exhibit cervical rigidity if the blood migrates into the intracranial subarachnoid space, simulating an intracranial subarachnoid hemorrhage. Variable neurologic deficits are present, depending on the magnitude and anatomic location of the hemorrhage. These deficits typically include extremity numbness, weakness, and sphincter dysfunction. Nuchal rigidity or signs of meningeal irritation also may be present.

**Diagnostic Strategies.** The diagnostic study of choice is MRI. Lumbar puncture also can confirm the presence of blood in the CSF.

**Differential Considerations.** Considerations in the differential diagnosis include epidural abscess, tumor, transverse myelitis, ischemia from an aortic catastrophe such as dissection, and anterior spinal artery thrombosis.

**Management.** Treatment depends on the etiology of the hemorrhage. Neurosurgical referral is obtained for further evaluation and for clot evacuation if compression is present. Angiography may be recommended if arteriovenous malformation is suspected.

**Syringomyelia**

**Principles of Disease.** *Syringomyelia* is the presence of a cavitary lesion within the substance of the spinal cord. A syrinx usually is a chronic progressive lesion, and its location within the cord determines the constellation of neurologic findings on examination.

**Clinical Features.** Headache and neck pain are the most common complaints, followed by sensory disturbance, gait disorder, and lower cranial nerve dysfunction. The classic pattern of sensory deficit involves a loss of pain and temperature sensation in the upper extremities, with preservation of proprioception and light touch. This phenomenon is described as a “dissociative anesthesia” because of the discrepant loss of sensory modalities. The sensory deficit often is described as being in a “cape-like” distribution over the shoulders and arms. The anatomic basis for the neurologic features of a syrinx is its location near the central canal. Here it may compress the crossing fibers of the lateral spinothalamic tract that carries pain and temperature fibers. Crude touch, position, and vibratory sensation typically are unaffected. Sensory fibers from the lower limbs are similarly spared.

The symptoms of syringomyelia develop and progress in accordance with the intracavitary pressure and location of the syrinx. The most common features on physical examination are lower limb hyper-reflexia, weakness and wasting in the hands and arms, dissociated sensory loss, and gait disorder. Symptoms may be exacerbated by a sneeze, cough, or Valsalva maneuver. Ninety percent of patients in whom this process develops have Arnold-Chiari I malformation (projection of cerebellar tonsils and medulla into the spinal canal). Syringomyelia also may result from spinal cord trauma (often months to years later) or compressive tumors, or may be a sequela of meningitis.

**Diagnostic Strategies.** Syrinx is best seen on MRI. No other study currently in widespread use is equal to MRI in diagnostic ability.

**Differential Considerations.** Considerations in the differential diagnosis for syrinx include intrinsic spinal tumor and demyelination.

**Management.** When the diagnosis of syringomyelia is considered, emergent imaging in the ED is not necessary if follow-up evaluation can be arranged, because this condition usually is a slowly progressive process. In patients for whom MRI studies are obtained and the diagnosis is made, referral to a neurosurgeon is indicated, because symptoms progress in approximately two thirds of patients.

**Idiopathic Spastic Paraparesis**

Idiopathic spastic paraparesis is a progressive disorder characterized by progressive weakness and signs of spasticity of the lower extremities. This condition sometimes also is referred to as primary lateral sclerosis, which describes the demyelination pattern in the lateral column of the spinal cord. This disorder typically occurs in older men. Sometimes a heritable form may be discovered. It is a diagnosis of exclusion.

**Human Immunodeficiency Virus Myelopathy**

HIV myelopathy typically occurs in patients with advanced HIV disease. Weakness, gait disturbance, sphincter dysfunction, sensory abnormalities, and signs of spasticity are features of this progressive process. This is a diagnosis of exclusion, because disorders such as toxoplasmosis, lymphoma, varicella zoster, and cytomegalovirus infection may produce a similar clinical picture in immunocompromised patients. Pathologically, vacuolization of myelin sheaths in the cord may be found. Treatment is directed at the retroviral infection, although there is no proven treatment.

**Spinal Cord Infarction**

Spinal cord infarction is another diagnosis of exclusion. Aortic dissection, surgery, and global ischemia are the more common causes, although this disorder may occur as a complication of systemic lupus erythematosus or may be cryptogenic. An
Extrrinic Cord Lesions

Spinal Epidural Hematoma

**Principles of Disease.** Spinal epidural hematoma is a relatively rare condition resulting from a variety of etiologic disorders. Its incidence is 0.1 to 100,000 population. The etiology may be traumatic, as after lumbar puncture or epidural anesthesia or associated with spinal surgery. Spinal epidural hematoma is more likely to occur in anticoagulated or thrombocytopenic patients or in patients with liver disease or alcoholism. Spontaneous bleeding is rare but may arise from spinal arterovenous malformation or vertebral hemangioma. Approximately one fourth to one third of all cases are associated with anticoagulation therapy, including low-molecular-weight heparin.

**Clinical Features.** The patient usually presents with sudden, severe, constant back pain with a radicular component. It may be noted to follow a straining episode. The pain may be worsened by percussion over the spine and maneuvers that increase intraspinal pressure, such as coughing, sneezing, or straining.

The pain often causes the patient to seek care before the development of neurologic signs, possibly leading to delays in diagnosis. Neurologic deficits follow and may progress over hours to days. Anticoagulant use or an intrinsic coagulopathy abnormality may be present.

The patient usually is in significant distress from the pain. Motor and sensory findings depend entirely on the level and size of the hematoma but can include weakness, paresis, loss of bowel or bladder function, and virtually any sensory deficit.

**Diagnostic Strategies.** MRI, as with virtually all suspected intraspinal disorders, is the diagnostic study of choice.

**Differential Considerations.** Considerations in the differential diagnosis include abscess, epidural neoplasm, acute disk herniation, and spinal subarachnoid hemorrhage.

**Management.** Recovery without surgery is rare, and surgical consultation for consideration of emergent decompressive laminectomy must be considered. The overall mortality rate is low (at approximately 8%). Functional recovery is related primarily to the length of time the symptoms are present. Recovery after 72 hours of symptoms is rare but has been reported even without surgery.

Spinal Epidural Abscess

**Principles of Disease.** Spinal epidural abscess is an infectious process usually confined to the adipose tissue of the dorsal epidural space, where there is a rich venous plexus. It is an uncommon disease, with an overall frequency of 0.2 to 1.2 per 10,000 hospital admissions. Major risk factors include diabetes, intravenous drug abuse, chronic renal failure, alcoholism, and immunosuppression. Although the disease may manifest in subacute or chronic forms, the acute presentation is seen most frequently in the ED. Thoracic and lumbar sites of infection predominate, with cervical epidural abscess being much less common. Infection typically extends over four to five spinal vertebral segments. The dura mater limits the spread of an epidural infection, making subdural or intraspinal spread uncommon. Hematogenous spread of infection to the epidural space is the most common source (seen in 26 to 50% of cases) either to the epidural space or to the vertebra with extension to the epidural space. Skin and soft tissue infections are the most frequently identified source (in 15%). Staphylococcus aureus is the most prevalent organism, being cultured in more than 50% of cases. Other frequently identified pathogens include aerobic and anaerobic streptococci, Escherichia coli, and Pseudomonas aeruginosa. Multiple organisms are identified in approximately 10% of cases; no organism is identified in 40%.

**Clinical Features.** The classic clinical presentation of spinal epidural abscess begins with a backache that progresses to localized back pain often associated with tenderness to percussion. Fever, sweats, and rigors are common, being reported in 30 to 75% of patients. The classic triad of back pain, fever, and progressive neurologic deficits is present in only a few patients, however, and delayed clinical diagnosis is common. Radicular symptoms may not be present initially but usually develop as the disease progresses.

Without treatment, myelopathic signs will develop, usually beginning with bowel and bladder disturbance. Weakness ensues, followed by paraplegia or quadriplegia. Approximately 10% of patients with spinal epidural abscess present with encephalopathy.

**Diagnostic Strategies.** MRI is the imaging modality of choice and needs to be performed emergently if the diagnosis is entertained. Other diagnostic testing is nonspecific for spinal epidural abscess, but a complete blood count may support the diagnosis, because leukocytosis commonly is present, with an average white blood cell count of 13,000/µL to 16,000/µL. The erythrocyte sedimentation rate, although not specific for epidural abscess, is virtually always elevated with this condition. Plain films usually are normal in appearance, unless evidence of osteomyelitis of an adjacent vertebral body is seen. Lumbar puncture is relatively contraindicated with known epidural abscess but often is performed as part of the evaluation for meningitis. CSF findings are consistent with a parameningeal infection, showing elevation of protein and some cellular response.

**Differential Considerations.** Any compressive spinal lesion, including tumor or hematoma, can mimic spinal epidural abscess.

**Management.** Urgent surgical consultation for decompression usually is required. Antibiotics effective against the most common pathogens (particularly S. aureus) should be started empirically. One such regimen that covers gram-positive and gram-negative organisms consists of a third-generation cephalosporin plus vancomycin, both given intravenously, plus rifampin given orally.

Outcome is related to the speed of diagnosis before the development of myelopathic signs. The disease is fatal in 18 to 25% of cases, and patients with neurologic deficit rarely improve if surgical intervention is delayed more than 12 to 36 hours after onset of paralysis. Patients operated on before development of neurologic symptoms have an almost universally good outcome.

Diskitis

**Principles of Disease.** Diskitis is an uncommon primary infection of the nucleus pulposus, with secondary involvement of the cartilaginous end plate and vertebral body. It may occur after surgical procedures or spontaneously, the latter being more common in pediatric patients. An increased incidence of diskitis has been noted in immunocompromised patients and in patients with systemic infections. Both an acute and a chronic disease course have been described, with the acute course being more common.

**Clinical Features.** Patients present with moderate to severe pain, localized to the level of involvement and exacerbated by
almost any movement of the spine. Radicular symptoms are present in 50 to 90% of cases.\textsuperscript{73,74} The lumbar spine is the most common site of disease. Elevated temperature is noted in more than 90% of patients.\textsuperscript{73} Patients experience pain with range of motion. Neurologic deficits are the exception with diskitis.

**Diagnostic Strategies.** Plain radiographs usually are not helpful for early diagnosis, but destruction of the disk space is highly suggestive if present. The radiographic findings become positive after 2 to 4 weeks of disease. In addition to disk space narrowing, plain films may show irregular destruction of the vertebral body endplates. Often there is a latent period (2 to 8 weeks) between the onset of back pain and the development of other clinical symptoms or abnormalities on the physical examination. MRI is the radiographic study of choice because it not only can diagnose diskitis but also can rule out paravertebral or epidural abscess. Laboratory studies often show an elevated erythrocyte sedimentation rate, but the white blood cell count usually is normal.\textsuperscript{73,74} *S. aureus* is the most common pathogen, but gram-negative, fungal, and tuberculous infections all have been recognized.

**Differential Considerations.** Considerations in the differential diagnosis include spinal epidural abscess, neoplasm, and hematoma.

**Management.** With timely diagnosis and treatment, outcome generally is good, and medical treatment with intravenous antibiotics usually is curative. Surgery often is not required.\textsuperscript{73,74}

**Neoplasm**

**Principles of Disease.** Spinal cord tumors are classified according to their relationship to the dura and spinal cord (extradural, intradural or extramedullary, and intradural or intramedullary). Spinal cord tumors produce neurologic symptoms by compression, invasion, or destruction of myelinated tracts. The resulting neurologic symptoms are directly related to the growth rate and the location of the tumor. Spinal cord tumors account for 4 to 10% of central nervous system tumors but for only 1% of all cancers. Primary tumors occur with an incidence of 1 per 1 million population.\textsuperscript{75} Most tumors of the spinal cord are metastatic in origin, however. Approximately 10% of patients with known cancer are diagnosed with a spinal metastasis at some point in the course of their disease, and 5 to 10% of patients ultimately diagnosed with cancer first present with a spinal metastasis.\textsuperscript{7} Lung cancer, breast cancer, and lymphoma account for more than 50% of the primary malignancies that subsequently develop spinal metastasis, spreading by the hematogenous route and direct extension. Most metastases occur in the thoracic spine, and nearly 20% of patients with tumor spread to the spine will be found to have disease at multiple levels.\textsuperscript{2,7,77}

**Clinical Features.** In 95% of patients with spinal neoplasm, the initial complaint is pain, either in the back at the level of the tumor or in a radicular distribution. Pain often is characterized as dull, constant, and aching and commonly is said to worsen with recumbency (in contrast with the pain of herniated disk).\textsuperscript{5} Nighttime pain that is severe is characteristic of spinal neoplasm.\textsuperscript{78} Any action that increases intraspinal pressure (Valsalva maneuver, sneeze, cough) may be associated with increased pain. Neurologic deficits vary, depending on the location of the lesion. Besides a thorough neurologic examination, a search for possible primary sites should be done on the physical examination.

**Diagnostic Strategies.** Plain radiographs are usually the initial diagnostic test, and 70 to 85% of patients with spinal column involvement show some abnormality on these films.\textsuperscript{78} Patients with neurologic abnormalities and suspicious findings on plain films are candidates for emergent MRI or CT myelography. In patients with a known history of neoplasm and new back pain, some authorities recommend foregoing plain films and proceeding directly to MRI, because plain films can be misleading or nondiagnostic.\textsuperscript{79}

**Differential Considerations.** Considerations in the differential diagnosis include any of the compressive lesions (blood, infection, tumor) as well as myelopathy due to neoplasm.

**Management.** Acute compressive myelopathy from neoplasm constitutes an oncologic emergency. Immediate treatment is required to preserve function and prevent deterioration. With onset of paraplegia and incontinence, less than 5% of patients regain ambulatory status.\textsuperscript{1,80} Of patients who are ambulatory at the time of diagnosis, 60% remain ambulatory.\textsuperscript{5} High-dose steroids, radiotherapy, and surgery all may be necessary acute interventions, and consultation with neurosurgeons, neurologists, oncologists, and therapeutic radiologists may be required.

---

**KEY CONCEPTS**

- Spinal cord disorders may manifest in subtle fashion and with nonspecific clinical signs and symptoms. In the absence of neurologic abnormalities or complaints, diagnosis of these disorders can be extremely difficult.
- Patients with rapid onset and progression of spinal cord symptoms should receive specialized imaging and consultation in the ED.
- MRI frequently is required to make a definitive diagnosis for spinal syndromes.
- With compressive lesions of the spinal cord, duration of neurologic dysfunction is directly related to ultimate neurologic outcome. The diagnosis must be made expeditiously and definitive therapy begun as soon as possible.

Chapter 105  Peripheral Nerve Disorders
E. Bradshaw Bunney and E. John Gallagher

PERSPECTIVE

Background
The nervous system is traditionally divided into central nervous system (CNS) and peripheral nervous system (PNS) components. The PNS can be further subdivided into 12 cranial and 31 spinal nerves. Disorders of the cranial nerves are discussed in Chapter 103. Because diseases of the neuromuscular junction and the myopathies are located distal to the neuron itself, they are also considered separately in Chapter 104. Radiculopathies, which are disorders of the roots of the PNS, are so commonly associated with musculoskeletal neck and back pain that they are mentioned only briefly here and are discussed in detail in Chapter 51.

The simplest approach to diseases of the PNS parallels the CNS model of separating focal from nonfocal disease. In the PNS, the first broad category is the focal group, which can be divided into those with evidence of single versus multiple lesions of peripheral nerves, known respectively as simple mononeuropathies and multiple mononeuropathies (or mononeuropathy multiplex). The second broad category, which constitutes the nonfocal group of peripheral neuropathies, contains the polyneuropathies. These tend to produce bilaterally symmetrical symptoms and signs, reflecting the widespread nature of the underlying pathologic process.

The evaluation of PNS disease involves a goal-directed history and physical examination targeted at answering the following three questions, each of which corresponds to a stratum of the algorithm presented in Fig. 105-1:

1. Are the sensorimotor signs and symptoms symmetrical or asymmetrical?
2. Are the sensorimotor signs and symptoms distal or both proximal and distal?
3. Is the modality involved exclusively motor, sensory, or mixed sensorimotor?

By systematically combining responses to these questions, one can identify seven discrete categories of peripheral neuropathy, each of which contains a finite set of possible diagnoses. Because pure motor or sensory findings tend to occur mainly in an asymmetrical, distal distribution, this is the only category in Figure 105-1 subdivided into pure motor and pure sensory abnormalities.

Epidemiology
Although Guillain-Barré syndrome (GBS) is the most commonly encountered emergent peripheral neuropathy in developed countries, its annual incidence is just over 1 to 2 cases per 100,000 population. In contrast to the low incidence of acute peripheral neuropathies, several of which are associated with short-term mortality, the vast majority of peripheral neuropathies seen in the emergency department (ED) are subacute or chronic and are associated not with mortality but with long-term morbidity.

Current estimates suggest that about 1.5% of the U.S. population suffers from peripheral neuropathy. Over 7% of the population has diabetes mellitus, with a prevalence rate of 20% in individuals older than 60 years. Roughly 50% of these individuals have peripheral neuropathy.

PRINCIPLES OF DISEASE

Anatomy
The spinal component of the PNS is shown schematically in Figure 105-2. The anterior and posterior nerve roots exit the spinal cord at each segmental level. Just distal to the dorsal root ganglion they converge to form a mixed (motor and sensory) spinal nerve, of which there are 31 pairs: 8 cervical, 12 thoracic, 5 lumbar, 5 sacral, and 1 coccygeal. The spinal nerves immediately bifurcate into anterior (ventral) and posterior (dorsal) rami. The posterior ramus travels to the back. The anterior ramus innervates the anterolateral portion of the body and supplies all peripheral nerves for the upper and lower extremities through the brachial and lumbosacral plexus, respectively. Interweaving of fibers occurs within a plexus, producing a mixed sensorimotor innervation of peripheral nerves exiting the plexus.

In addition to the motor and sensory modalities of the PNS, the autonomic nervous system has a peripheral component. Anatomically and functionally, the autonomic nervous system is divided into two parts: a sympathetic (thoracolumbar) component and a parasympathetic (cranosacral) component. Autonomic dysfunction may cause systemic abnormalities, such as orthostasis, or local problems, such as atrophic, dry skin.

Pathophysiology
The PNS has only three basic responses to a wide array of pathologic stimuli. As shown in Figure 105-2, these are (1) the myelinopathies, where the primary site of involvement is limited to the myelin sheath surrounding the axon; (2) the axonopathies, where the primary site of involvement is the axon, with or without secondary demyelination; and (3)

Figure 105-2. Schematic representation of macroscopic and microscopic anatomy of the peripheral nervous system and its interface with the central nervous system. See text for explanation.

The neuronopathies, where the cell body of the neuron itself is the primary site of involvement, ultimately affecting the entire peripheral nerve. Although overlap occurs, each of these prototypes has a distinctive clinical presentation, electrophysiologic profile, and microscopic appearance.

Electrophysiologic testing, that is, nerve conduction studies (NCSs) and needle electromyography (EMG), detects underlying pathologic abnormalities. Because neither test is readily available in the acute care setting, they are discussed only briefly here. Information gathered from NCSs and EMG can be used to obtain objective information on the anatomic distribution of involvement (symmetrical vs. asymmetrical and distal vs. proximal and distal) and the modalities involved (sensory, motor, or mixed). NCSs and EMG can also identify the level of the neuraxis affected by the disease process (i.e., root, plexus, or nerve); if the nerve is affected, electrophysiologic testing can help determine whether the lesion is mono- or polyneuropathic. Finally, EMG and NCSs can distinguish axonal from myelinopathic disease, further narrowing the differential diagnosis. Prognosis is determined by the nature of pathologic involvement of the PNS. Primary demyelination spares the axon and thus carries the best prognosis. The prognosis is worse in axonopathies because reestablishing nerve function is dependent on the much slower process of axonal regeneration. Neuronopathies, which begin
with primary destruction of the nerve cell body, produce pure motor or pure sensory syndromes. Eventually the entire nerve is affected, resulting in the worst prognosis of the three.

### Clinical Features

The differential diagnosis for any patient presenting with sensory, motor, or sensorimotor complaints, particularly if localized to the extremities, should include a peripheral neuropathy. Within this group, patients with focal weakness are most concerning because they are at greatest risk for respiratory compromise. Box 105-1 lists the causes of acute, emergent weakness that may affect respiration. Although several of the disorders listed are myopathies (see Chapter 106) rather than peripheral neuropathies, they are lumped together because it is important to identify patients at risk for respiratory failure early in the course of evaluation.

As soon as the emergent causes of weakness have been excluded—which is possible in the majority of patients—the individuals with focal weakness should be assessed next to exclude CNS disease (e.g., stroke) (see Chapter 99). One can then proceed through the systematic approach to peripheral neuropathy outlined in Figure 105-1. Another way to look at the algorithm displayed in Figure 105-1 is shown in Table 105-1, with the distinguishing features of each of the seven peripheral neuropathic patterns described by distribution and modality and represented by a disease prototype.

### Type 1: Demyelinating Polyneuropathies

The pattern of symmetrical weakness, usually worse distally, accompanied by variable sensory findings is characteristic of acute GBS. This pattern is discussed first because it is the most common cause of weakness associated with acute respiratory failure seen in emergency practice.

**GUILLAIN-BARRÉ SYNDROME**

GBS is a heterogeneous and unpredictable disorder, with marked variation in latency between antecedent infection and symptom onset. The clinical signs, cadence of disease progression, degree of respiratory compromise, laboratory findings, and time required for convalescence are also highly variable. The most common form of GBS is an acute inflammatory demyelinating polyneuropathy (AIDP), comprising 90% of the cases seen in the United States. Less common variants include acute motor axonal neuropathy (AMAN), acute motor and sensory axonal neuropathy (AMSAN), and the Miller Fisher syndrome. AMAN accounts for most of the remaining cases seen in the United States afflicting those of Asian decent. Miller Fisher syndrome is a rare form of GBS characterized by the triad of ophthalmoplegia, ataxia, and areflexia (Box 105-2). The majority of patients seek treatment days to weeks after resolution of an upper respiratory or gastrointestinal illness, presenting with progressive, symmetrical distal (and usually to a lesser extent proximal) weakness. Signs and symptoms are usually worse in the lower extremities and are associated with diminution or loss of deep tendon reflexes (DTRs), variable sensory findings, and sparing of the anal sphincter. Up to 32% will have all four extremities affected at the time of presentation and 10% will have weakness that begins in the upper extremities.
extremities. However, the ocular muscles are usually spared. Urinary retention secondary to autonomic dysfunction may occur, contributing to a clinical picture easily mistaken for a spinal cord lesion or conus medullaris syndrome.

The most commonly infectious organisms associated with GBS are *Campylobacter jejuni* (in patients with a history of diarrhea), cytomegalovirus, Epstein-Barr virus, and *Mycoplasma pneumoniae*. AIDP is caused in part by macrophage invasion of the myelin sheath. The macrophage is believed to detect antigens in the myelin that are nearly identical to the antigens present on certain infectious organisms.

In practice, patients with symmetrical weakness of relatively acute onset, decreased or absent DTRs, and variable degrees of sensory loss should be managed as if they have GBS or one of its variants, which places them at risk for respiratory compromise. Conversely, patients with predominantly sensory signs and symptoms are less likely to develop acute respiratory distress and have a more favorable prognosis.

About half of patients with GBS have autonomic dysfunction, experience a peak of disease severity within a week of onset, have some form of cranial nerve involvement (usually VII), and suffer long-term sequelae of their illness. Nearly one third require ventilatory support. Both the mortality and the recurrence rate are about 3%.

In addition to electrophysiologic testing, there are three ancillary tests that may be helpful in the diagnosis of GBS. Cerebrospinal fluid (CSF) analysis is useful when it demonstrates the characteristic picture of markedly elevated protein with only a mild pleocytosis. In the clinical setting of suspected GBS, this finding is highly specific. Early in the disease, however, patients may have normal CSF values. Consequently, a normal CSF cannot be used to exclude GBS because of the limited sensitivity of this test. Selective enhancement of the anterior spinal nerve roots on magnetic resonance imaging (MRI) is suggestive, but not diagnostic, of GBS. The GBS disability score, which combines age, presence or absence of diarrhea, and a score of the patient’s ability to ambulate independently at 2 weeks, has been shown to be predictive of prognosis at 6 months, particularly related to independent activity.

**Management.** Individuals with suspected GBS must have their respiratory function tested. A decrease in forced vital capacity (FVC) has been shown to correlate with the need for intubation in patients with GBS. An FVC of less than 20 mL/kg was associated with pending respiratory failure and the need for intubation, whereas patients with an FVC of greater than 40 mL/kg did not require intubation. Likewise, patients with a negative inspiratory force (NIF) of less than 30 cm water are more likely to require mechanical ventilation. Other tests, such as the forced expiratory volume in 1 second (FEV₁) or peak flow rate (PFR) can also be used to assess respiratory function. Patients unable to perform these tests and those with less than 100% of predicted values should have an arterial blood gas obtained. Evidence of alveolar hypoventilation (elevated carbon dioxide [Pco₂]) in a patient with an unsecured airway requires a level of intensive monitoring that is impractical in many emergency departments. Therefore, patients with weakness, CO₂ retention, or other evidence of early ventilatory failure should be considered for early, prophylactic intubation.

Among patients with possible GBS who have normal pulmonary function, extensor neck strength can be monitored to predict impending ventilatory failure. Patients with probable GBS should receive neurologic consultation and be admitted to the hospital. Either plasma exchange or intravenous immunoglobulin (IVIG) should be administered. There is sound evidence that both are superior to placebo and that combination or sequential therapy confers no therapeutic advantage over either intervention alone. Plasma exchange is cumbersome and not available at many hospitals. IVIG is more readily available and is usually administered in a dose of 400 mg/kg/day for 5 days. However, IVIG is quite expensive, costing roughly $50 to $80 per gram. Although not approved by the Food and Drug Administration, IVIG is supported in certain national guidelines. Corticosteroids are no longer recommended for treatment of GBS. Oral steroids have been shown to delay recovery. Intravenous steroids alone have been shown to impart no benefit, and though the combination of intravenous steroids and IVIG has hastened recovery, there was no affect on long-term outcome. The marked elevation in blood pressure seen in some patients with GBS should not be treated because it is typically transient and may be followed by precipitous and unpredictable hypotension.

**Type 2: Distal Symmetrical Polyneuropathies**

Most polyneuropathies are characterized by a pattern of distal, symmetrical sensorimotor findings, worse in the lower than upper extremities, with a stocking-glove distribution of sensory abnormalities that gradually diminishes as one moves proximally. The motor findings and loss of DTRs, which lag behind the sensory features, follow a similar pattern of progression from distal to proximal. The diffuse, distal, symmetrical nature of this pattern is most consistent with a toxic-metabolic disease process, as yet unidentified, that causes a length-dependent axonopathy. Distal symmetrical polyneuropathy (DSPN) is the most common type of peripheral neuropathy seen in emergency practice. Only the most common causes of DSPN are discussed, with a more complete listing of causes shown in Box 105-3.

**Diabetic Distal Symmetrical Polyneuropathy**

The preponderance of cases of DSPN occur in diabetics, also termed diabetic polyneuropathy. Initial symptoms usually consist of “positive” sensory complaints (e.g., dysesthesias such as tingling or burning) beginning on the plantar surfaces of both feet. At the early stages of a typical DSPN, there may be some asymmetry. At this juncture, it may be impossible to distinguish a focal neuropathic process such as a mononeuropathy from a polyneuropathy, although in this location, prior probability strongly favors a polyneuropathy. As the process advances, the plantar surfaces of both feet become dysesthetic before the dorsum of either foot is involved. Weakness of dorsiflexion of the big toe is usually the first motor sign, followed by weakness of foot dorsiflexion, footdrop, loss of Achilles’ reflex, and later a “steppage gait.”
Sensory loss continues to move proximally, and before it reaches the knees, the fingertips are usually involved. DTRs are progressively lost, as is proprioception. If the latter becomes severe, patients may develop sensory ataxia. As the neuropathy continues to progress, sensory abnormalities ultimately involve all modalities and extend to a diamond-shaped periumbilical area. Far advanced disease may affect sensation over the skull vertex and facial midline structures. Atrophy and areflexia occur as weakness worsens. Severely impaired patients may be unable to ambulate or grasp objects. These symptoms have a significant impact on the patient’s quality of life, affecting not only physical functioning but emotional, sleep, and social functioning. Many of these patients display signs of depression or anxiety. Polyneuropathies can be difficult to diagnose and are best approached by performing electrodiagnostic studies on patients with a constellation of symptoms and signs suggesting a particular neuropathy. Polyneuropathies can be difficult to diagnose and are best approached by performing electrodiagnostic studies on patients with a constellation of symptoms and signs suggesting a particular neuropathy. Polyneuropathies can be difficult to diagnose and are best approached by performing electrodiagnostic studies on patients with a constellation of symptoms and signs suggesting a particular neuropathy.

**Management.** As with virtually all peripheral neuropathies, referral is indicated for management of diabetic DSPNs. If discomfort is severe, the etiology of the neuropathy seems likely to be diabetic, and if referral is delayed, it may be necessary to provide the patient with some symptomatic relief. Because treatment of neuropathic pain has traditionally been linked to etiology rather than an underlying mechanism, the choice of pharmacologic agents is empirical, with substantial practice variation in the United States and worldwide. In the United States the first choice is often a nonsteroidal anti-inflammatory drug, which has little proven efficacy and a high potential for renal impairment. Based on placebo-controlled randomized clinical trials, tricyclic antidepressants and anticonvulsants appear to have the best NNTs (number of patients needed to treat in order to provide at least 50% relief of symptoms in one patient). These are generally in the range 3 to 5, with confidence intervals whose upper limits reach 10 in some instances. Imipramine or amitriptyline may be started at a dose of 25 mg at bedtime (10 mg in elderly patients) and titrated slowly up to a dose of 300 mg. Carbamazepine at a dose of 200 to 400 mg every 8 hours or gabapentin at a dose of 900 to 3600 mg/day are also effective treatments. Although tramacol is a mixed opioid, development of dependence in long-term use appears to be uncommon. In a recently published guideline, the following medications were recommended for the treatment of neuropathic pain: gabapentin, opioids, tramadol, and tricyclic antidepressants. Also being used is pregabalin at 150 to 600 mg/day, with a mechanism similar to that of gabapentin, and dulexetine at 60 mg/day, which is a selective serotonin and norepinephrine reuptake inhibitor. Among the selective serotonin reuptake inhibitors (SSRIs), paroxetine and bupropion appear to be effective, but fluoxetine is not. The summary NNT for the SSRIs has a confidence interval that reaches 50, suggesting that, pending further data, these agents should be considered second-line drugs. Topical capsaicin provides relief in some patients, but the burning associated with its application has limited its usage. Improving glycemic control can prevent, diminish, or reverse early diabetic DSPNs. Patients will typically spend over $1,000 per year for pain relief from diabetic DSPN.

**Alcoholic Distal Symmetrical Polyneuropathy**

Although the association between alcoholism and peripheral neuropathy has been well established for centuries, demonstration of a direct neurotoxic effect of alcohol remains elusive. The preponderance of evidence, from both observational studies in humans and experimental data from animal models,

- Pernicious anemia (vitamin B₁₂)
- Pyridoxine deficiency (vitamin B₆)
suggests that the association between alcohol and peripheral neuropathy may be confounded by nutritional status (i.e., deficiency states might be the true underlying cause of alcoholic peripheral neuropathy).

The clinical and pathologic picture of alcoholic neuropathy is similar to that of the DSPN of diabetes. However, in alcoholism severe myopathy and cerebellar degeneration often complicate the clinical picture. Autonomic skin changes with atrophy and hair loss accompany the sensorimotor abnormalities. Often other systemic effects of alcoholism are so severe that the patient may not notice the neuropathic symptoms. All patients with suspected alcoholic DSPN should receive dietary supplements and referral for outpatient management.

Human Immunodeficiency Virus Neuropathies

With the widespread use of highly active and effective antiretroviral treatment, peripheral neuropathies have become the most common neurologic complication of HIV infection. The typical HIV neuropathy is a DSPN, which appears to be triggered by a combination of dideoxynucleoside therapy and poorly characterized immune-mediated mechanisms associated with HIV. These patients require referral for specialized care. In addition to standard therapies for DSPN, lamotrigine has been shown to be moderately effective in the treatment of HIV-associated painful neuropathies.

Toxic and Metabolic Neuropathies

Many toxic agents and metabolic derangements produce a typical DSPN. Box 105-3 lists some of the most common toxic and metabolic causes of peripheral neuropathy. On the basis of preliminary results from a case-control study, the statins have been added to this list.

**Type 3: Asymmetrical Proximal and Distal Peripheral Neuropathies (Radiculopathies and Plexopathies)**

Radiculopathies are discussed in detail in Chapter 103. Plexopathies, which are discussed briefly in this chapter, are uncommon and often the result of trauma (Box 105-4). Generally, a plexopathy, whether brachial or lumbosacral, is identified by a process of elimination (i.e., a pattern of sensorimotor and reflex abnormalities that fit neither a radicular nor individual peripheral nerve distribution). Although this approach does not exclude a mononeuropathy multiplex on physical examination alone, a careful history should determine whether the patient is at risk for developing a mononeuropathy or plexopathy on the basis of underlying disease.

Most plexopathies are often the result of blunt trauma and are usually seen in young men following motor vehicle accidents. Most present for evaluation several months after injury because of the need to recover from concurrent injuries. Therapeutic intervention is often delayed in order to maximize the potential for spontaneous recovery. Several surgical repairs exist, including neuromatization or nerve transfer.

Radiation (actinic) plexopathy occurs after a variable period of latency following treatment, which may extend to 20 years or more. Almost all series include women who received radiation treatment for breast cancer. Among neoplastic causes, most originate from the lung or breast. Patients with probable neoplastic brachial plexopathy need imaging studies and may require immediate radiation therapy. Pain control is the focus of management.

Thoracic outlet syndrome remains a controversial disorder.

Although the pendulum has swung over the past 50 years from a postulated vascular cause to a neurogenic etiology, current evidence supporting the high prevalence of compression of the brachial plexus as a cause of thoracic outlet syndrome is in fact only slightly better than earlier evidence favoring a vascular etiology. Nevertheless, the disorder is currently felt to be most commonly due to compression of the medial or lower portion of the brachial plexus by a cervical rib or fibrous band. The syndrome is characterized by gradually progressive weakness and wasting of median and ulnar hand muscles with ulnar forearm and hand sensory signs and symptoms. Patients with this clinical picture should be referred for NCSs and EMG, which are said to be diagnostic. The treatment of true neurogenic thoracic outlet syndrome requires surgical removal of the rib or aberrant fibrous band to decompress the brachial plexus. An excellent discussion of this entity from a different perspective can be found in Chapter 85.

Because of the complexity of plexopathies, there is no reason to expect that one can or should do more in the ED than localize the probable pathologic process to the brachial or lumbosacral plexus. Depending on severity and suspected etiology, one should either admit or refer the patient to a neurologist with experience in PNS disease.

**Type 4: Isolated Mononeuropathies**

The pattern of asymmetrical, sensorimotor, usually distal, peripheral neuropathy is characteristic of a mononeuropathy. Mononeuropathies are of two main types: isolated and multiple. The isolated mononeuropathies are discussed in this section, while the multiple mononeuropathies, also termed...
Isolated mononeuropathies, are discussed in the next section, as a type 5 peripheral neuropathy.

Isolated mononeuropathies are usually caused by trauma, either blunt or penetrating (Box 105-5). If the trauma is blunt, the injury may be secondary to compression from an internal or external source. Entrapment neuropathies are a subset of compression neuropathies occurring at anatomic locations where nerves traverse potentially constricting compartments or tunnels. Isolated mononeuropathies may be acute, intermittent, or chronic and continuous. Antecedent peripheral neuropathy may be a risk factor for development of compression neuropathy (so-called double-crush syndrome), particularly in diabetics.

Radial Mononeuropathy

The radial nerve arises from C5-T1 roots. After exiting the brachial plexus, it passes behind the proximal humerus in the spiral groove and takes a lateral (radial) course down the upper arm (Fig. 105-3). At about the level of the antecubital fossa, it bifurcates into the posterior interosseous (pure motor) and superficial radial (pure sensory) nerves.

The radial nerve controls extension of the fingers, thumb, wrist, and elbow (triceps). In contrast to the median and ulnar nerves, the radial nerve provides only extrinsic motor innervation to the hand (i.e., it does not supply motor fibers to any muscles that both originate and insert within the hand). In further contrast to the median and ulnar nerves, which supply most of the sensation to the hand, the radial nerve makes a contribution only to a cutaneous dorsal area overlaying the first dorsal interosseous muscle, sometimes extending part of the way up the dorsa of the thumb, index, and long fingers.

Radial mononeuropathy caused by involvement at the level of the axilla is uncommon. When it occurs, it is usually associated with other upper extremity mononeuropathies or a brachial plexopathy. Although improper use of crutches may cause this syndrome, it usually occurs after an extended period of unconsciousness during which the arm is positioned in such a way that prolonged, deep compression is applied to the axilla. Axillary radial mononeuropathy is distinguished from the more common humeral form by the finding of triceps involvement in addition to typical wrist and finger drop. Triceps involvement occurs because the innervation to the triceps is proximal to the point where the nerve is most vulnerable as it winds around the humeral shaft (see Fig. 105-3).

Most radial mononeuropathies are due to so-called Saturday night palsies. The euphemism is derived from the association of radial mononeuropathy with improper positioning of the arm during deep, commonly inebriated sleep. Consequently, the radial nerve is trapped for a prolonged period between the humeral shaft and some firm surface, causing an external compression mononeuropathy. “Bridegroom’s palsy” is another eponym for radial mononeuropathy, so named because the radial nerve may be compressed by the bride’s head resting on the bridegroom’s arm during sleep.

Because innervation of the wrist and finger extensors occurs distal to this area of the humeral shaft, findings are characterized by wrist and finger drop and mild numbness over the skin of the first dorsal interosseus muscle. Depending on the level,
degree, and duration of compression, some fascicles of the nerve may remain functional, resulting in a partial radial mononeuropathy. Thus, the superficial radial nerve may remain intact, resulting in no loss of sensation, or loss of wrist and finger extension may be incomplete.

Because the finger drop of radial mononeuropathy places the hand at a mechanical disadvantage, examination of ulnar function by testing interossei may produce false-positive findings of weakness. To adjust for this, the examiner should ask the patient to place the palm on a horizontal supporting surface such as a stretcher. With the fingers extended and no longer “dropped” at the metacarpophalangeal joints, interosseous strength can now be fairly tested. Failure to perform this maneuver may cause misdiagnosis of a simple radial mononeuropathy as a brachial plexopathy in an effort to explain what appears to be radial and partial ulnar nerve involvement.

About 90% of radial nerve palsies occurring during sleep, coma, or anesthesia recover fully, usually within 6 to 8 weeks. Evidence of denervation on EMG studies predicts a slower rate of recovery. Tourniquet injuries to the radial nerve usually recover spontaneously within 2 to 4 months. If axonal degeneration is seen on electrophysiologic testing, recovery may take longer, although virtually all radial mononeuropathies caused by tourniquets eventually resolve. About 75% of radial nerve injuries associated with a closed humeral shaft fracture recover spontaneously. In contrast, surgical intervention is needed to free the nerve from entrapment associated with complex fractures.

While patients are waiting for spontaneous recovery to occur, the hand should be maintained in about 60 degrees of dorsiflexion. Although a simple dorsal plaster or fiberglass splint treats the wristdrop, atrophy and contractures can be minimized, and function of the hand can be improved if wide rubber bands anchored to the splint at a point proximal to the wrist are attached to individual fingers to provide passive dorsiflexion.

Ulnar Mononeuropathy

The ulnar nerve includes C7-T1 roots and passes through the brachial plexus to descend medially, without branching, to the ulnar (medial) condylar groove at the elbow. It then enters the cubital canal, where it gives off branches to the ulnar wrist flexor and the deep flexors of the fourth and fifth digits.

Just proximal to the wrist, two important sensory branches leave the main trunk to supply cutaneous sensation to part of the hand (Fig. 105-4). These are the palmar and dorsal cutaneous branches, which do not pass through Guyon’s canal. The palmar branch supplies sensation to the hypothenar eminence and the dorsal branch innervates the ulnar side of the dorsum of the hand, extending out nearly to the tip of the fifth and ulnar half of the fourth digit.

At the wrist, the nerve enters Guyon’s canal (Fig. 105-5) between the pisiform and hook of the hamate, then bifurcates into the superficial terminal sensory branch and the deep motor branch.

The superficial sensory nerve supplies ulnar sensation to the palmar side of the fifth and half of the fourth digit (see Fig. 105-5). The deep motor nerve supplies the hypothenar muscles, then crosses to the radial side of the palm to innervate

Figure 105-4. Ulnar nerve, major branches, right arm, anterior view. (From Stewart JD: Focal Peripheral Neuropathies, 3rd ed. Philadelphia, Lippincott Williams & Wilkins, 2000.)

Figure 105-5. Distal ulnar nerve and branches, right hand, palmar view. Numbers indicate four main sites of distal ulnar mononeuropathy in the wrist and hand. *Denotes hypothenar branches. (From Stewart JD: Focal Peripheral Neuropathies, 3rd ed. Philadelphia, Lippincott Williams & Wilkins, 2000.)
the ulnar intrinsics (all interossei and the ulnar lumbricals of the fourth and fifth digits), terminating in the first dorsal interossei. The interossei abduct and adduct the fingers and are all innervated by the ulnar nerve. The lumbrical muscles flex the metacarpal phalangeal joints and are evenly divided between the ulnar (fourth and fifth) and median (second and third) digits. The ulnar nerve can be thought of as the complement to the median nerve in the hand because it supplies all of the muscles and all palmar sensation not innervated by the median nerve.

The ulnar nerve may be injured at two locations near the elbow: in the ulnar condylar groove and distally in the cubital canal. Because the condylar groove is shallow, the ulnar nerve runs superficially in this location and is vulnerable to injury, usually from external pressure or from a fracture or dislocation. The ulnar nerve has a propensity to develop a “tardy ulnar palsy,” occurring years after a traumatic event. Many of these delayed ulnar mononeuropathies can be localized to the elbow on electrophysiologic testing.

Some ulnar mononeuropathies occur secondary to compression just proximal to entry into the cubital canal or are entrapped within the canal itself. Transient symptoms may occur during prolonged flexion or with repeated flexion and extension at the elbow.

Although distinguishing a condylar from a cubital ulnar mononeuropathy is difficult, it is usually possible to localize the problem to the region of the elbow or the wrist. In addition to prior probability heavily favoring the elbow, the presence of sensory abnormalities in an ulnar distribution in the hand and fingers (i.e., usually including the fifth digit and “splitting” the fourth digit) strongly suggests that the lesion is at the level of the elbow rather than the wrist. The ulnar cutaneous innervation to the hand branches off from the main trunk proximal to the nerve entering Guyon’s canal (see Figs. 105-4 and 105-5). Thus, a lesion at the wrist should not produce sensory abnormalities, whereas one at the elbow would be expected to do so.

Compression of the ulnar nerve within Guyon’s canal is rare. When it does occur, it affects all of the ulnar intrinsics (i.e., the two ulnar [fourth and fifth] lumbricals) and all the interossei. However, the ulnar extrinsics (i.e., the deep flexors of the fourth and fifth digits) are not affected, nor is the ulnar flexor of the wrist. The only sensory abnormalities are those in the distribution of the superficial terminal sensory branch, sparing other areas of ulnar innervation (see Fig. 105-5).

There are three ulnar mononeuropathies that occur distal to Guyon’s canal in the hand. The two most common ones involve the deep terminal branch, either proximal or distal to the separation of the hypothenar branches (see Fig. 105-5). If the lesion is proximal, it produces weakness of all the ulnar innervated muscles of the hand without sensory loss. If it is distal, the hypothenar ulnar intrinsics are spared but the innervated muscles of the hand without sensory loss. If it is expected to do so.

Figure 105-6. Median nerve, major branches, right arm, anterior view. (From Stewart JD: Focal Peripheral Neuropathies, 3rd ed. Philadelphia, Lippincott Williams & Wilkins, 2000.)

**Median Mononeuropathy**

The median nerve arises from C5-T1 spinal nerve roots and exits the brachial plexus through the lower trunk (Fig. 105-6). Median mononeuropathy is usually diagnosed as carpal tunnel syndrome (CTS), which is the most common of all entrapment neuropathies. CTS has a prevalence of 3 to 6% in the U.S. population. Although the patient may complain of bilateral symptoms, a careful history usually reveals that symptoms in one hand preceded those in the other. Awakening at night and shaking the hand is a common symptom of CTS. Symptoms are often worsened by activity. For unclear reasons, the pain may spread as high as the arm or shoulder, although the parasthesias are generally confined to the fingers. Many patients on initial questioning state that their entire hand is involved, although this is not supported by careful sensory examination. Complaints that the hands are clumsy or weak, especially when holding a glass or opening a screw-top container, are frequent. The skin of the fingers innervated by the median nerve may be drier and rougher to the touch than the corresponding ulnar skin, depending on the duration of entrapment.

When there is motor involvement in CTS it is confined to the median intrinsics, which innervate the lumbricals (flexion of the metacarpal phalangeal joints), and subserve thumb opposition, abduction, and flexion, known as the LOAF muscles. However, the hallmark of CTS is sensory involvement, with motor abnormalities occurring later. The typical pattern of sensory innervation of the hand by the median, ulnar, and radial nerves shows marked individual variation.
The most specific finding for CTS is splitting of the fourth digit (i.e., normal sensation of the ring finger on the ulnar palmar side with abnormal sensation on the median [radial] palmar side of the same finger). The most sensitive finding is abnormal sensation of the distal palmar tip of the index finger. If sensory findings are absent in the presence of motor findings consistent with median nerve involvement, it is highly unlikely that the patient has CTS, and an alternative diagnosis should be sought. If neither sensory nor motor symptoms are evident, none of the provocative tests originally reported to reproduce the sensory symptoms of CTS—of which the most common are Tinel’s sign (percussion of the median nerve at the wrist) and Phalen’s sign (maximal palmar flexion at the wrist)—has shown adequate sensitivity or specificity to determine which patients should be referred for electrodiagnostic studies. As suggested earlier, the best way to examine patients for sensory findings is to touch the distal palmar tips very lightly, asking the patient whether the sensation feels “abnormal.”

CTS appears to be associated with the conditions listed in Box 105-6. Of these, the two most common are diabetes mellitus and pregnancy. CTS associated with systemic illness is commonly bilateral. Although CTS in pregnancy may be self-limiting, about half the women in one series were still symptomatic at 1-year follow-up. All patients with suspected CTS should be referred for NCSs. However, because of the dissociation between clinical and electrodiagnostic indicators of CTS early in the disease, patients with normal electrodiagnostic findings in the presence of symptoms suggestive of CTS (with or without signs) should have an MRI or sonogram. At present, the sensitivity of MRI is good but its specificity is poor. Ultrasound has shown to be useful particularly in patients with symptoms and a negative NCS. This is done by measuring the cross-sectional area of the median nerve at the end of the pisiform. Thus, if all diagnostic studies in a symptomatic patient are negative, or if only the MRI result is positive, they should be repeated within a few months if symptoms do not resolve. This recommendation is based on the theory that the CTS will progress over time to the point that an objective indicator such as the NCS will become positive.

Because of the possibility of development of a disabling “median hand” after inadvertent direct injection of the median nerve, one should not inject the carpal tunnel with steroids in the ED. The physician to whom the patient is referred can decide after NCS whether to recommend splinting, injection, or surgical division of the transverse carpal ligament. Endoscopic repair appears to provide excellent results.

### Sciatic Mononeuropathy

The sciatic nerve includes L4-S3 spinal nerve roots that pass through the lumbosacral plexus and divide into two terminal branches: the common peroneal and tibial nerves. The nerve exits the pelvis through the sciatic notch, passes behind the hip, and remains deep in the thigh until its terminal bifurcation at the proximal popliteal fossa (Fig. 105-7).

Lesions of the sciatic nerve occur with posterior hip dislocation or with virtually any form of penetrating or blunt trauma that causes formation of a buttock hematoma. Other causes include deep gluteal injection and prolonged supine immobilization on a firm surface. Because the sciatic nerve innervates the hamstrings and provides all sensorimotor function distal to the knee, a complete sciatic mononeuropathy is a devastating injury. Ambulation is extremely difficult because of inability to flex the knee and a flail foot (i.e., neither flexion nor extension is possible at the ankle). Fortunately, many sciatic mononeuropathies are incomplete. For unknown reasons, a partial lesion typically involves only the trunk of the sciatic nerve, which subsequently becomes the common peroneal nerve, sometimes making the two difficult to distinguish from one another clinically. On electrophysiologic studies, evidence of involvement of gluteal muscles or of any muscles innervated by the tibial nerve readily distinguishes a partial sciatic mononeuropathy from a lesion of the common peroneal nerve. Treatment of footdrop requires a posterior splint to maintain the ankle at 90 degrees until a brace can be obtained (see later section on “Common Peroneal Mononeuropathy”).

### Lateral Femoral Cutaneous Mononeuropathy

Lateral femoral cutaneous mononeuropathy (meralgia paresthetica) is a common syndrome believed to be caused by injury to this pure sensory nerve as it passes through or over the inguinal ligament, where it may become entrapped or kinked. Along with facial nerve neuropathy, meralgia paresthetica is
one of the most commonly reported mononeuropathies associated with HIV. External pressure and obesity may also contribute to nerve injury, causing numbness and dysesthesia over the skin of the upper lateral thigh. Regression usually occurs spontaneously, but recurrence is common and may require a release procedure for the inguinal ligament.

Common Peroneal Mononeuropathy

The common peroneal nerve is a continuation of one trunk of the sciatic nerve. It is most vulnerable to injury where it winds around the fibular neck (Fig. 105-8). It then passes through the fibular canal and bifurcates into its terminal branches, the superficial and deep peroneal nerves. The superficial peroneal nerve innervates the peroneal muscles (foot everters) and supplies sensation to the lateral, distal lower leg and dorsum of the foot. The deep peroneal nerve traverses the anterior compartment and supplies innervation to the dorsiflexors of the foot and toes, plus cutaneous sensation between the first and second toes.

Most common peroneal mononeuropathies are idiopathic and thought to be related to compression where the nerve is superficially located lateral to the fibular neck. Because this common neuropathy is often noted on awakening, it may be secondary to position during sleep. Leg crossing may also be a risk factor for development of this mononeuropathy. The most striking feature of a complete common peroneal mononeuropathy is footdrop caused by weakness of foot dorsiflexion. At testing, the everters of the foot are also weak, but the inverters, which are innervated by the tibial nerve, remain strong. This is the single most reliable clinical feature distinguishing sciatic from common peroneal mononeuropathy. Analogous to radial mononeuropathy in the upper extremity, sensory abnormalities in the leg and foot are inconstant and easily overlooked in peroneal mononeuropathy. Most patients with peroneal palsy do not require timely surgical exploration and repair performed. Blunt trauma may cause a mononeuropathy indirectly by entrapment of a nerve within a fracture, hematoma, or compartment, requiring surgical intervention. Alternatively, nerves may be injured at a point where they are superficial, either by a single direct blow or by sustained pressure caused by immobility (pressure palsies). Most of these resolve spontaneously over time, depending on the severity of injury and length of the nerve. If entrapment can be confirmed by imaging or electrophysiologic studies, a release procedure is indicated. In many instances, when there is disagreement between clinical and EMG findings, MRI may be helpful in selecting patients for exploration by visualizing entrapment or traction.54 Characteristic sonographic findings have also been reported in several mononeuropathies.55

The mononeuropathies that do not require timely surgical exploration should be referred for further workup to confirm the location of the neuropathic lesion.

Type 5: Mononeuropathy Multiplex

Mononeuropathy multiplex is characterized by an asymmetrical, sensorimotor, usually distal pattern of peripheral neuropathy (Box 105-7). As with isolated mononeuropathies, sensory abnormalities tend to be located in the same general anatomic region as the accompanying motor findings. Whether DTRs are affected depends on which nerves are involved. For example, if the process includes the femoral nerve, the patellar reflex is likely to be diminished or absent.

**BOX 105-7 MONONEUROPATHY MULTIPLEX**

- Vasculitis
  - Systemic vasculitis
  - Polyaerteritis nodosa
  - Rheumatoid arthritis
  - Systemic lupus erythematosus
  - Sjögren’s syndrome (keratoconjunctivitis sicca)
  - Nonsystemic vasculitis
- Diabetes mellitus
- Neoplastic
  - Paraneoplastic
  - Direct infiltration
- Infectious
  - Lyme disease
  - HIV
- Sarcoid
- Toxic (lead)
- Transient (polycythemia vera)
- Cryoglobulinemia (hepatitis C)
Vasculitis

Mononeuropathy multiplex is strongly associated with vasculitis, which is the most common indication for sural nerve biopsy in most series. However, because diabetes mellitus is far more prevalent than vasculitis, the most common cause of mononeuropathy multiplex among ED patients is diabetes.

Diabetes Mellitus

Although the role of ischemia in diabetic neuropathies is controversial, evidence for a vascular cause is stronger in the asymmetrical diabetic multiple mononeuropathies than in the more common DSPNs seen in diabetes.

Lyme Disease

The PNS manifestations of Lyme disease can be divided into early and late. The early PNS syndromes commonly include facial nerve involvement (rarely other cranial nerve palsies) and radiculoneuritis. Late PNS involvement occurs as a DSPN, mononeuropathy multiplex, or radiculoneuropathy. The most common neurologic abnormality in Lyme disease is unilateral or bilateral facial nerve palsy, usually occurring within a month of exposure. Patients may also complain of headache and constitutional symptoms. Early in the course of Lyme disease, severe neuritic pain may develop in a radicular distribution, often in or near the dermatome where the tick bite occurred. There may also be associated sensory changes, motor weakness, and decreased reflexes consistent with nerve root involvement. Patients with chronic Lyme disease present with sensory symptoms, particularly distal paresthesias in the lower extremities. Less commonly, they develop a picture consistent with mononeuropathy multiplex or a radiculopathy. The latter is much less severe than the early radiculoneuritis of Lyme disease.

The most useful diagnostic tests for patients with suspected Lyme disease are a serum enzyme-linked immunosorbent assay, Western blot, and CSF examination. CSF abnormalities suggestive of Lyme disease are a lymphocytic pleocytosis, elevated protein, and normal glucose. The CSF is almost always abnormal in early radiculitis, sometimes abnormal with isolated facial palsy, and typically normal in chronic Lyme disease. Facial nerve palsy without CSF abnormalities may be treated with oral doxycycline 100 mg twice a day for 2 weeks. Intravenous ceftriaxone is the drug of choice for all other neurologic syndromes associated with Lyme disease. The adult dosage is 2 g/day, and the pediatric dosage is 75 to 100 mg/kg/day. Treatment with ceftriaxone should be continued for at least 2 weeks.

Type 6: Amyotrophic Lateral Sclerosis

Although amyotrophic lateral sclerosis (ALS) and motor neuron disease (MND) are often used synonymously, the latter represents a spectrum of diseases ranging from primary lateral sclerosis, in which degeneration is confined to upper motor neurons, to progressive muscle atrophy, in which only lower motor neurons are involved. ALS, which requires the presence of both upper and lower motor neuron findings, resides in the middle of this spectrum, representing the most common form of MND. The incidence of ALS is 1.5 to 2.5 per 100,000.56

In ALS, the primary pathologic process in the PNS component of the disease is a neuronopathy of the anterior horn cell. Because this structure is located proximal to the point where motor and sensory fibers merge to form mixed spinal nerve roots, the signs and symptoms of MND are purely motor (see Fig. 105-2). In the CNS, there is a loss of Betz cells from the motor cortex with secondary degeneration of the corticospinal tracts. Box 105-8 lists some representative upper, lower, and mixed motor signs. Patients typically demonstrate asymmetric distal weakness without sensory findings. Positive motor phenomena in the form of fasciculations are found in almost all patients at diagnosis but are rarely an initial complaint. Although there is electrophysiologic evidence of autonomic involvement in ALS, this is generally subclinical.

Most patients with an asymmetrical, distal, pure motor neuropathy have ALS, for which only supportive treatment is currently available. However, there are some preliminary studies of recombinant human insulin–like growth factor 1 that have shown marginal improvement in this otherwise fatal disease.57 All patients in whom this diagnosis is suspected should be referred for electrophysiologic confirmation against standardized criteria. Confirmation is particularly important because multifocal motor neuropathy, a rare disease that masquerades as ALS, responds dramatically to cyclophosphamide and immunoglobulin administration.58

Type 7: Sensory Neuronopathy (Ganglionopathy)

This category of peripheral neuropathy is characterized by a selective or predominant involvement of the dorsal root ganglion, producing a relatively pure sensory syndrome analogous to the pure motor syndrome of ALS. Although all sensory modalities are affected, proprioception is profoundly altered, leading to sensory ataxia and loss of DTRs without weakness. The distribution is typically asymmetrical and distal at the outset, but depending on severity and extent of progression, it may become functionally symmetrical. Sensory ganglionopathies can now be confirmed by MRI of the spinal cord and surrounding areas, showing degeneration of central sensory projections that localize the disease process to the dorsal root ganglion.59 Some of the more common causes of this type of peripheral neuropathy are listed in Box 105-9.
### ANTHROPOLY DIAGNOSTIC TESTING

Relatively few blood tests contribute to the diagnosis of peripheral neuropathy, and only a small number of these are available in the ED. CSF analysis may be helpful in GBS and Lyme disease. Additional tests that may be indicated in patients referred for evaluation are listed in Box 105-10, along with others that may be ordered selectively, depending on the clinical picture. Expensive batteries of tests purporting to measure a wide variety of antibodies to components of peripheral neuropathies are commercially available but have not been shown to be useful as screening tests.

### KEY CONCEPTS

- In the emergency department, it is not usually possible to arrive at the diagnosis of a specific peripheral neuropathy because of the need for confirmatory ancillary testing that is beyond the scope of emergency practice. Rather, the focus should be on identifying one of seven categorical patterns of peripheral neuropathy, shown in Figure 105-1 and listed in Table 105-1, after other non-PNS causes have been eliminated.
- One of these seven patterns can usually be identified by combining three clinical features that are readily obtainable from a goal-directed history and physical: (1) right-left symmetry or asymmetry, (2) proximal-distal location, and (3) sensorimotor modalities affected. This approach is summarized as an algorithm in Figure 105-1.
- Identification of one of the seven types of peripheral neuropathy determines the need for ancillary diagnostic testing, therapeutic intervention, disposition, and the timing of neurologic referral.
- Respiratory compromise is the primary life-threatening event seen in some peripheral neuropathies; GBS is by far the most common peripheral neuropathic cause of respiratory arrest.
- Any patient with symmetrical weakness, distributed both proximally and distally, with loss or diminution of DTRs and variable sensory abnormalities should be treated as having GBS.

The references for this chapter can be found online by accessing the accompanying Expert Consult website.
Disorders of the neuromuscular unit can result in clinical presentations that range from subtle symptoms to acute respiratory failure. Morbidity and mortality are often related to failure of the muscles that maintain airway integrity and drive respiration. In most cases, the pathophysiology of these disorders is well understood and permits an organization and understanding that is based on the level of the nervous system affected. This facilitates an approach that is based on signs and symptoms, the findings of which direct the urgency of diagnostic testing and treatment.

Processes involving the brainstem and brain can usually be differentiated from those in the spinal cord and in the peripheral nervous system on the basis of historical and physical findings. In general, lesions at the level of the brainstem or above produce unilateral weakness; bilateral weakness caused by lesions above the spinal cord is generally associated with a change in mental status or cranial nerve involvement. Lesions of the central nervous system result in upper motor neuron signs that include spasticity, hyperreflexia, and extensor plantar reflexes. As a corollary, when bilateral upper motor neuron signs are found in conjunction with normal mental status, diagnostic testing including neuroimaging should focus on looking for a lesion in the spinal cord.

The neuromuscular unit has four components: the anterior horn cells of the spinal cord, the peripheral nerve, the neuromuscular junction, and the muscle being innervated. The level of the pathology determines associated signs and symptoms (Table 106-1). Myelopathies involve the spinal cord; radiculopathies involve the nerve roots as they leave the spinal cord; neuropathies involve the peripheral nerves; and myopathies involve the muscle. The use of physical signs to differentiate these disorders is discussed in Chapter 11.

Neuropathies involve the axon itself or the myelin sheath (or the Schwann cells that make the myelin sheath) of the nerve. Nerve conduction studies can differentiate the locations of involvement. As the conduction along the axon is disrupted, the subsequent delay in transmission first causes symptoms in the muscles controlled by longer nerve axons, resulting in a history of weakness beginning in the distal extremities. As the myelin destruction or axonal degeneration progresses, patients usually note a slowly progressive course of symptoms.

The motor nerve branches into multiple terminals as it approaches the muscle. The neuromuscular junction is composed of the presynaptic membrane, the postsynaptic membrane, and the synaptic cleft. The neurotransmitter is acetylcholine (ACh). The motor synapse is a nicotinic receptor, whereas muscarinic synapses link the central nervous system with the autonomic nervous system. Disorders of the postsynaptic nicotinic receptors produce weakness. Postsynaptic ACh receptors are continually turned over at a rate that is related to the amount of stimulation. A disorder of transmission often leads to increased production of ACh receptors. Myasthenia gravis (MG) is the prototype of neuromuscular junction diseases.

The history of patients with complaints of weakness focuses on the acuity and progression of onset and the potential for airway compromise. Any complaint of difficulty breathing or swallowing raises suspicion of bulbar involvement and concern for life-threatening deterioration. The history must elicit whether the weakness is muscular or nonspecific generalized fatigue. Weakness implies the inability to exert normal force, whereas fatigue implies a decrease in force with repetitive use. When muscular weakness exists, the clinician should determine whether it is focal or generalized, proximal or distal. The history of present illness must include the duration of symptoms, exacerbating and mitigating factors, and presence of associated symptoms such as fever, weight loss, and bowel or bladder changes.

Historical elements might explain the presenting complaint: a preexisting neuromuscular disorder that could lead to deterioration; prior episodes or a family history of weakness suggesting periodic paralysis; a recent respiratory or diarrhea illness suggesting a postinfectious, autoimmune process such as transverse myelitis or Guillain-Barré syndrome (GBS); a cancer history suggesting a metastatic tumor as the cause of a compressive myelopathy; a food or travel history suggesting botulism or tick exposure.

The physical examination should first assess the patient’s airway and ventilation and then proceed to localize the level...

Myelopathy
Without upper motor neuron function, muscle weakness is present with increased spinal reflexes, including an extensor plantar reflex (Babinski's response). Muscle tone initially ranges from normal to slightly increased, eventually leading to spasticity as a late finding. The same reflex arcs eventually create spasticity in the affected muscles. The weakness is ascending in nature, and there is often bladder and bowel involvement. When sensory findings are present, they often define the level of the lesion. The presence of bowel or bladder dysfunction, or diminished sensation, localizes the lesion to the spinal cord. The presence of pain often connotes a compressive lesion such as a herniated intravertebral disk, epidual hematoma, abscess, or tumor. Acute, painless spinal cord lesions include transverse myelitis and spinal cord infarction.

Motor Neuron Disease
Amyotrophic lateral sclerosis is the prototypical disease process resulting from a degeneration of the motor neuron without sensory involvement. These patients may complain of dysarthria or dysphagia; however, the characteristic findings are those of combined upper and lower motor neuron dysfunction. Consequently, findings include hyperreflexia, muscle wasting, and fasciculation. Pain is not a component of the clinical picture.

Poliomyelitis affects the anterior horn cells and results in lower motor neuron disease without sensory involvement. The presence of fasciculations. Box 106-1 provides the grading system used in motor strength assessment. Table 106-2 provides the findings used to distinguish upper motor neuron from lower motor neuron processes.

Differential Considerations

Myelopathies

A patient with myelopathy shows signs of upper motor neuron dysfunction. Without upper motor neuron function, muscle weakness is present with increased spinal reflexes, including an extensor plantar reflex (Babinski's response). Muscle tone initially ranges from normal to slightly increased, eventually leading to spasticity as a late finding. The same reflex arcs eventually create spasticity in the affected muscles. The weakness is ascending in nature, and there is often bladder and bowel involvement. When sensory findings are present, they often define the level of the lesion. The presence of bowel or bladder dysfunction, or diminished sensation, localizes the lesion to the spinal cord. The presence of pain often connotes a compressive lesion such as a herniated intravertebral disk, epidural hematoma, abscess, or tumor. Acute, painless spinal cord lesions include transverse myelitis and spinal cord infarction.

Box 106-1

3 = Moves against gravity but unable to resist examiner  
2 = Moves but unable to resist gravity  
1 = Flicker but no movement  
0 = No movement

of the lesion. The presence of swallowing and a strong cough suggests that the patient has sufficient protective and ventilatory reserve. The muscles used to lift the head off the bed may weaken before those of respiration and should be assessed. A patient who is not yet intubated but is complaining of shortness of breath or difficulty breathing should have frequent vital capacity measurements. Normally, these values range from 60 to 70 mL/kg. When the forced vital capacity reaches 15 mL/kg, intubation is necessary. If vital capacity cannot be measured, a maximal negative inspiratory force (NIF) is easily determined. An NIF less than 15 mm Hg suggests the need for endotracheal intubation. A bedside assessment used to follow ventilatory status is to have the patient count numbers with one breath. With sequential performance of this test, a decline in respiratory function is detected as the patient fails to count as high as before. Arterial blood gas is not necessarily helpful because functional reserve can be severely diminished by the time a patient develops either hypercarbia or hypoxia.

The assessment of vital signs is important because some causes of weakness may result in dysregulation of the autonomic system. A systematic neurologic examination should assess the patient’s mental status, cranial nerves, motor function, sensory function, deep tendon reflexes, and coordination, including cerebellar function. The motor examination begins by determining whether the weakness is unilateral or bilateral and which muscle groups are involved. Key components of the examination include motor strength, muscle bulk, and presence of fasciculations. Box 106-1 provides the grading system used in motor strength assessment. Table 106-2 provides the findings used to distinguish upper motor neuron from lower motor neuron processes.

*Not significant but can occur.
weakness can be symmetrical or more often asymmetrical. Patients initially have a clinical picture similar to that of viral meningitis, with fever and neck stiffness. Currently, most cases follow exposure of an immunocompromised host to the oral polio vaccine, and this should be sought in the history. The cerebrospinal fluid analysis resembles that of viral meningitis.

Neuropathies

Weakness from a neuropathy is often noted first in distal muscles and then ascends. Decreased grip strength or footdrop may be noted first. Muscle tone ranges from slightly diminished to flaccid. As all outflow from the spinal cord is affected, deep tendon reflexes are diminished or absent. Patients exhibit varying degrees of altered sensation, muscle wasting, and fasciculation depending on the duration of the symptoms. Disorders that should be considered include GBS, toxic neuropathies, diabetic neuropathy, and tick paralysis (which is caused by inhibition of both nerve conduction and function of the neuromuscular junction).

Diseases of the Neuromuscular Junction

Disorders of the neuromuscular junction cause progressive motor fatigability. The initial depolarization of the muscle causes stimulation of a maximum number of receptors, producing a normal, or nearly normal, strength response. Repeated stimulation leads to diminishing motor strength, which is caused by the blockage of the receptors (as in MG) or by a decrease in the amount of ACh released (as in botulism) or by inactivating Ach by irreversibly binding with it (as in organophosphate poisoning). A decrease in the release of ACh may produce a combination of nicotinic and muscarinic effects leading to anticholinergic findings such as decreased visual acuity, confusion, urinary retention, tachycardia, low-grade fever, and dry, flushed skin. In the case of Lambert-Eaton myasthenic syndrome, weakness is more pronounced at the beginning of muscle use and improves with repeated use as more ACh builds up in the synaptic cleft with each stimulation. Diseases of the neuromuscular junction should be considered in patients who present with generalized weakness in association with an acute cranial nerve deficit. Muscle tone is generally diminished and sensation is preserved.

Myopathies

Myopathies produce generalized, symmetrical weakness. Reflexes are present but diminished, muscle tone is usually diminished, but sensation is preserved. Myopathies caused by inflammatory disorders (polymyositis, dermatomyositis, polymyalgia rheumatica, and viral myositis) cause muscle pain and tenderness. Metabolic disorders affecting muscle strength (e.g., electrolyte and endocrine disorders) are painless in nature.

Diagnostic Strategies

Laboratory Studies

Serum potassium, calcium, and phosphorus should be assessed in patients with acute weakness. Thyroid function tests are recommended in cases of suspected myopathies. A creatine kinase (CK) level assesses for muscular inflammation; a urinalysis should be performed for the presence of myoglobinuria and possible rhabdomyolysis.

Special Studies

Magnetic resonance imaging (MRI) is the preferred test for suspected cases of acute myelopathy. Computed tomography of the spinal cord with myelography can help to differentiate compressive (herniation, abscess, tumor) from noncompressive causes when MRI is not available. Cerebrospinal fluid analysis is indicated when GBS or transverse myelitis is suspected.

Specific Disorders

Disorders of the Neuromuscular Junction

Myasthenia Gravis

Perspective. It is rare for the emergency physician to diagnose a new case of MG; more commonly, patients with established disease present with exacerbations of their disease that must be recognized and addressed. In addition, the emergency physician must be aware of medication interactions in patients with MG.

Principles of Disease. MG is a rare disorder that affects approximately 60,000 Americans. Age of onset is bimodal, with the first peak among women 20 to 40 years of age and a second peak among men 50 to 70 years old.

MG results from autoantibodies directed against the nicotinic acetylcholine receptor (AChR) at the neuromuscular junction. This leads to complement-mediated destruction of AChRs with a decrease in the total number of available receptors. The autoantibodies further compete with ACh for binding at remaining receptors. Thus, with repeated stimulation of the same muscle, fewer and fewer sites are available and fatigue develops.

Fatigability and muscular weakness are the hallmarks of MG. Considering the slow clinical progression of MG and the low likelihood of short-term complications from its progression, the importance of suspecting the diagnosis is to facilitate proper referral for further evaluation.

Clinical Features. Ocular symptoms are often the first manifestation of MG. The typical symptoms are ptosis, diplopia, or blurred vision. Ocular muscle weakness is the first sign in up to 40% of patients, although 85% of patients with MG eventually have ocular involvement. When present, ptosis is often worse toward the end of the day. Respiratory failure is rarely the initial symptom of MG. Even so, up to 17% of patients may have weakness of the muscles of respiration. Bulbar muscles may be involved, producing dysarthria or dysphagia. Lambert-Eaton myasthenic syndrome is a rare disorder in which almost 50% of cases are associated with small cell carcinoma of the lung. Autoantibodies cause inadequate release of ACh from nerve terminals, affecting both nicotinic and muscarinic receptors. With repeated stimulation, the amount of ACh in the synaptic cleft increases, leading to an increase in strength, the opposite of that seen with MG. The classic syndrome includes weakness that improves with use of muscles, particularly proximal hip and shoulder muscles; hyporeflexia; and autonomic dysfunction, most commonly seen as dry mouth. Management primarily focuses on treating the underlying neoplastic disorder, although IVIG has been reported to be useful.

Diagnostic Strategies

New-Onset Myasthenia Gravis. The diagnosis of MG is based on clinical findings and a combination of serologic testing, electromyographic testing, and the bedside edrophonium or ice bag tests. Serum testing for AChR antibodies is positive in 80 to 90% of patients with MG, but not available in the emergency department setting.
The edrophonium test and ice bag tests are similar to perform and the results are based on their effect on the ptosis seen in patients with suspected MG. The production of edrophonium was discontinued in early 2008 and it will no longer be available once current stores are depleted. Edrophonium is a short-acting acetylcholinesterase (AChE)-blocking agent that produces an increase of ACh in the synaptic cleft and a reduction in ptosis after intravenous administration. With the ice bag test, cooling decreases symptoms in MG while heat exacerbates symptoms. In both tests, the change in the amount of ptosis is measured before and after the application of edrophonium or an ice bag. The distance from the upper to the lower eyelid in the most severely affected eye is measured first. If edrophonium is given, an intravenous test dose of 1 to 2 mg is given first as some patients have a severe reaction. If no adverse reaction is found and the patient does not dramatically improve in 30 to 90 seconds, a second dose of 3 mg is given. If there is still no response, a final dose of 5 mg is given for a total maximum dose of 10 mg. Atropine should be available at the bedside during the test. Because of the potential for cholinergic-induced increased airway secretions, this test should be used with caution in asthmatics and patients with chronic obstructive pulmonary disease. If an ice pack is used, it is applied to the affected eye for approximately 2 minutes, and the distance between the lids is measured again. A prospective evaluation of the ice bag approach found the test result to be positive (an improvement in distance of at least 2 mm) in 80% of patients with MG and in no patients without MG.

Myasthenic Crisis. Myasthenic crisis is defined as respiratory failure leading to mechanical ventilation. It occurs in 15 to 20% of patients with MG, usually within the first 2 years of disease onset. Although it is potentially life-threatening, the mortality from this complication of MG has declined dramatically with better and more aggressive ICU care and the use of plasmapheresis (PE) and/or immunomodulatory therapy with high-dose intravenous immunoglobulin (IVIG) and corticosteroids.

Underlying infection, aspiration, and medication changes—stopping anticholinergic medications or taking a new medication that precipitates weakness—most often set off crisis, but the precipitant may not be found in up to 30% of cases. Other precipitants can be surgery and pregnancy (Box 106-2).

The initial step in managing the patient in crisis is stabilization of the airway. In less severe cases in which intubation is not imminent, it is imperative to monitor ventilatory status pending intensive care unit admission through forced vital capacity or NIF measurement. Noninvasive ventilation with biphasic positive airway pressure may be effective in managing patients who need ventilatory support.

Signs of myasthenic crisis should be sought in all patients with MG, even when they do not complain of weakness. Many commonly used drugs can adversely affect patients with MG (see Box 106-2). A patient with stable MG who has an acute medical or surgical condition requires a full neurologic examination. The decision to admit or discharge a patient with MG from the emergency department should take into account the potential for neurologic deterioration.

Management

Cholinesterase Inhibitors. Pyridostigmine (60–120 mg every 4–6 hours) and neostigmine (15–30 mg every 4–6 hours) prolong the presence and activity of ACh in the synaptic cleft. They are the backbone of chronic outpatient therapy and provide symptomatic improvement. The most common side effects are those of excessive cholinergic stimulation, such as increased airway secretions and increased bowel motility. At extremes there may be bradycardia or even worsening of weakness, simulating a myasthenic crisis. These drugs are often used as adjunctive therapy to control symptoms while other therapy is being instituted, after which they are often discontinued.

The use of intravenous pyridostigmine in the setting of acute exacerbation is controversial and not recommended because PE or IVIG is recommended. Cholinergic drug therapy is not recommended for the treatment of MG in the emergency department.

Immunosuppressant Drugs. Immunosuppressant drugs are often used for the chronic control of MG. Although they have no role in the acute management of a myasthenic crisis, they may be started before extubation of a patient recovering from crisis. Cochrane Database reviews in 2005 and 2007 found support for the use of corticosteroids but only limited evidence that cyclosporine and cyclophosphamide and azathioprine improve MG.

Of note, the initiation of corticosteroids in patients with moderate to severe weakness may actually precipitate a worsening of weakness or even myasthenic crisis.

Thymectomy. While the association between thymoma and MG is not fully elaborated, it is well known that thymectomy for patients with thymoma can lead to remission of MG or enable a reduction in other medications. Thymectomy for patients with MG but without thymoma has been shown to have similar benefits and is recommended for patients younger than 60 with remission or improvement in up to 50% of cases and is supported by a clinical policy of the American Academy of Neurology. The onset of improvement after thymectomy is often delayed for 2 to 5 years.

Immunomodulatory Therapy. PE and IVIG can be used for patients with exacerbations of MG or preoperatively in patients with stable MG.

PE removes the AChR antibodies and other immune complexes from the blood. The fall in AChR levels is associated with improvement in symptoms of MG. There is a risk of complications from hypotension or anticoagulation. Because of safety concerns, clinical trials have not been done in children. Although there are no randomized controlled studies, a review yielded many case series with short-term benefit, especially in myasthenic crisis, and it is recommended by the American Academy of Neurology.

A review of IVIG trials found one randomized controlled trial of IVIG versus placebo that demonstrated the benefit from IVIG. Another trial failed to show a difference between
Botulism

Principles of Disease. Botulism is a toxin-mediated illness that can cause acute weakness leading to respiratory insufficiency. The Centers for Disease Control and Prevention (CDC) reports that an average of 145 cases are reported each year: 15% are foodborne, 65% are infant botulism, and 20% are wound related.\textsuperscript{17} Clostridium botulinum is an anaerobic, spore-forming bacterium. Three of eight known toxins produced by C. botulinum (types A, B, and E) cause human disease. There has been an increase in the incidence of botulism from wound infections. In a 4-day period in 2003 in Washington State, four people contracted wound botulism from black tar heroin.\textsuperscript{18} Botulism is also thought to be a potential agent for bioterrorism. The botulinum toxin works by binding irreversibly to the presynaptic membrane of peripheral and cranial nerves, inhibiting the release of ACh at the peripheral nerve synapse. As new receptors are generated, the patient improves.

Clinical Features. The toxin blocks both voluntary motor and autonomic functions. Because the disorder is at the neuromuscular junction, there is no sensory deficit and no sense of pain. The onset of symptoms is 6 to 48 hours after the ingestion of tainted food. There may or may not be accompanying signs and symptoms of gastroenteritis, with nausea, vomiting, abdominal cramps, diarrhea, or constipation. The classic feature of botulism is a descending, symmetrical, flaccid paralysis. The muscles often affected first are the cranial nerves and bulbar muscles, and the patient presents with diplopia, dysarthria, and dysphagia, followed later by generalized weakness. There may be associated blurring of vision. Because the toxin decreases cholinergic output, anticholinergic signs may be seen in the form of constipation, urinary retention, dry skin and eyes, and increased temperature. Pupils are often dilated and not reactive to light. This can be a point of differentiation from MG. Deep tendon reflexes are normal or diminished.

Infantile botulism results from the ingestion of C. botulinum spores that are able to germinate and produce toxin in the high pH of the gastrointestinal tract of infants. The same spores are not active in the gut of adults because of the lower pH. The CDC reports approximately 100 cases per year.\textsuperscript{19} It occurs in infants between the ages of 1 week and 11 months and has been implicated as a cause of sudden infant death syndrome. Because spores can survive in honey, it is recommended that honey not be fed to infants. The clinical presentation includes constipation, poor feeding, lethargy, and weak cry; consequently, this diagnosis must be in the differential diagnosis of the floppy infant.

Diagnostic Strategies. The diagnosis is made by both clinical findings and exclusion of other processes. The toxin can be identified in serum and stool, but the assay is not commonly available in most hospitals and requires a prolonged turnaround time. If the suspected food source is available, it should also be tested for the toxin.

Management. The treatment is initially focused on stabilizing the airway and supportive measures. There is an equine antitoxin that can shorten the disease course, although it is not clear that the antitoxin decreases ventilator dependence and there is a risk of anaphylaxis and serum sickness. Nevertheless, the antitoxin should be administered as soon as possible. The toxin is available through the CDC by calling (404) 329-2888. An intravenous human botulism immune globulin (BIG-IV) has been developed for treatment of infantile botulism\textsuperscript{20} and is available through the California Department of Health Services Infant Botulism Treatment and Prevention Program on-call physician at (510) 231-7600.

Tick Paralysis

Principles of Disease. The pathogenesis of tick paralysis, also known as tick toxicosis, is not fully understood. It is known that a toxin is injected while the tick feeds, and it is referred to as an ixo-toxin. The toxin appears to diminish the release of ACh at the neuromuscular junction and also reduces nerve conduction velocity. It may also have effects at autonomic ganglia, leading to pupillary signs. According to the CDC, the state of Colorado reports on average one case per year, though in 2006 four cases were reported during one week.\textsuperscript{21}

Clinical Features. Tick paralysis is an acute, ascending, flaccid motor paralysis that can be confused with GBS, botulism, and MG. It typically begins with the development of an unsteady gait, followed by ascending, symmetrical, flaccid paralysis. Although symptoms usually begin 1 to 2 days after the female tick has attached and begun to feed, delays of up to 6 days have been reported.\textsuperscript{22} There may be associated ocular signs, such as fixed and dilated pupils, that can help distinguish it from GBS.

Management. The management is supportive care and tick removal. A tick can be removed using forceps to grasp it as closely as possible to the point of attachment. Care must be taken not to leave mouth parts in the patient’s tissue. Although symptoms may resolve rapidly after removal of the tick, supportive measures such as intubation should not be withheld pending resolution of symptoms.

Disorders of the Muscles

Perspective

Newly acquired weakness originating at the muscular level can be divided into two types: inflammatory and toxic-metabolic. Inflammatory disorders usually produce pain and tenderness, but metabolic disorders do not.

Inflammatory Disorders

Principles of Disease. The most common inflammatory myopathies are polymyositis (PM) and dermatomyositis (DM). PM may be idiopathic in nature, occur secondary to infections (viral or bacterial), or be seen in conjunction with other disorders such as sarcoidosis or hypereosinophilic syndromes. Inflammatory myopathies cause weakness, pain, and tenderness of the muscles involved. They must be distinguished from simple myalgias related to a fever or cramping that may suggest myopathic, or be seen in conjunction with other disorders such as sarcoidosis or hypereosinophilic syndromes. Inflammatory myopathies cause weakness, pain, and tenderness of the muscles involved. They must be distinguished from simple myalgias related to a fever or cramping that may suggest myopathy (inability to relax the muscle).

Clinical Features. DM and PM can occur at any adult age, although DM may also affect children. There is a slightly increased incidence in women. An associated increased risk of malignancy, especially breast, ovary, lung, gastrointestinal, and lymphoproliferative disorders, has been noted after the diagnosis of DM or PM, although the reported rate of malignancy varies widely. Proximal muscle weakness predominates and leads to complaints of difficulty rising from a seated position or climbing stairs and weakness in lifting the arms over the head. There is often pain and tenderness in these proximal muscles as well. There is a decrease in reflexes as the weakened muscles fail to contract. Thus, the decrease in reflexes is in proportion to the decrease in strength. Fasciculations are not seen, and atrophy is a very late finding.
DM is similar to PM, but it is also associated with classic skin findings. These are more prominent in childhood but are also found in adults. They include a periorbital heliotrope and erythema and swelling of the extensor surfaces of joints. The facial rash is usually photosensitive and may also involve the exposed areas of the chest and neck.

**Diagnostic Strategies** Electrolyte abnormalities must be ruled out and the serum CK checked. If possible, the skeletal muscle isoform (MM) should be distinguished from the cardiac muscle isoform (MB). The CK must be interpreted in light of the entire clinical picture. The presence of an elevated CK does not establish the cause of weakness as a myopathy because some neuromopathies can also produce an elevated CK. Similarly, a normal CK does not rule out a myopathy as the cause of weakness. Electromyography and muscle biopsy are used to confirm the diagnosis.

**Management.** PM and DM are usually managed with oral prednisone in a dose of 1 to 2 mg/kg/day. When steroids prove ineffective and during acute exacerbations, cytotoxic drugs such as azathioprine or methotrexate are added. Fortunately, the degree of rhabdomyolysis seen with the inflammatory myopathies is not sufficient to cause renal impairment.

**Metabolic Disorders**

**Perspective.** Acute, generalized muscle weakness can be seen with severe electrolyte abnormalities of any cause: hypokalemia, hyperkalemia, hypocalcemia, hypercalcemia, hypomagnesemia, and hypophosphatemia. Acute painless myopathies can also be seen with endocrine disorders involving the thyroid, parathyroid, or adrenal glands.

Of particular interest are several disorders referred to collectively as the periodic paralyses. This group of entities includes familial periodic paralysis (FPP) of the hyperkalemic and hypokalemic forms and thyrotoxic periodic paralysis (TPP), which is similar to hypokalemic FPP except that it is associated with hyperthyroidism.

**Periodic Paralysis**

**Principles of Disease.** These are autosomal-dominant disorders of ion channels resulting in intermittent attacks of flaccid extremity weakness associated with either hyperkalemia or hypokalemia, although the latter is more common. It is most often associated with an inherited genetic mutation. Patients usually report a personal and family history of similar episodes.

**Clinical Features and Diagnostic Strategies.** Patients may suffer either isolated or recurrent episodes of flaccid paralysis. The lower limbs are involved more often than the upper, although both can be affected. Bulbar, ocular, and respiratory muscles are usually not involved. Onset is rapid; a prodrome of myalgias and muscle cramps may occur but is uncommon; mental status and sensory function are typically preserved, but reports of sensory nerve involvement have been documented. Males are more often affected than females, and there is a higher incidence in Asians, particularly Japanese, although it occurs in other ethnic groups.

Attacks may be induced by the injection of insulin, epinephrine, or glucose. The onset of symptoms often follows a high carbohydrate intake (with subsequent insulin rise) and a period of rest. A typical complaint is the acute onset of weakness noted on waking in the morning after a large meal the preceding evening. An electrocardiogram, which should be done immediately in all patients suffering from acute paralysis, demonstrates signs of hyperkalemia or hypokalemia. An immediate potassium level should be ordered; in the hypokalemic form, the potassium level during an attack falls to values below 3.0 mEq/L.

**Management.** Many cases resolve spontaneously with supportive care alone. The mainstay of management is the treatment of the underlying electrolyte imbalance. In the hypokalemic state the total body potassium is not depleted but has shifted intracellularly. Thus, in the repletion of potassium, caution is necessary to prevent overtreatment. For this reason, intravenous potassium should be used sparingly; one or two 10-mEq doses of potassium chloride (KCl), each administered over 1 hour, should be the maximum given intravenously. This can be done in parallel with 40 mEq oral potassium repletion and retesting of serum potassium levels. Intravenous hydration helps to redistribute the body’s potassium stores.

**Thyrotoxic Periodic Paralysis.** The clinical picture of TPP is almost identical to that of hypokalemic FPP, and indeed a small number of patients with hypokalemic FPP have hyperthyroidism. In TPP, symptoms related to hyperthyroidism are often present at the same time the patient develops weakness. The relation of the hyperthyroidism to hypokalemia is probably due to increased sodium-potassium adenosine triphosphatase activity, which causes a rapid shift of potassium from the extracellular to the intracellular compartment. Treatment of the hyperthyroid symptoms, such as tachycardia, may help the treatment of the paralysis as well. There are case reports of TPP in which the patient’s weakness did not respond to potassium replacement until propranolol was given to treat tachycardia. There is probably a genetic feature underlying this disorder because there is a higher incidence of repeated attacks of hypokalemic periodic paralysis among Japanese and Chinese patients with hyperthyroidism. It is important that all patients have thyroid function testing done after a first episode of hypokalemic paralysis.

---

**KEY CONCEPTS**

- The approach to evaluating patients with acute neuromuscular weakness is facilitated by first determining the location of the lesion (spinal cord, nerve, neuromuscular junction or muscle) and then considering the most common disorders that affect the area in question.
- In patients with bilateral upper motor neuron signs and a normal mental status, neuroimaging of the spinal cord should be strongly considered.
- In patients presenting with acute neuromuscular weakness, complaints of difficulty in breathing or swallowing should heighten suspicion of bulbar involvement with possible airway compromise. In such patients, a forced vital capacity less than 15 mL/kg or a maximal NIF less than 15 mm Hg are potential indications for mechanical ventilation.
- Botulism usually arises as a painless descending paralysis, often first affecting the cranial nerves and bulbar muscles, without sensory deficits or significant alteration of consciousness. The treatment is airway management and administration of antitoxin.

The references for this chapter can be found online by accessing the accompanying Expert Consult website.
CNS infections comprise a broad spectrum of disease entities. Meningitis is defined as inflammation of the membranes of the brain or spinal cord and is also called arachnoiditis or leptomeningitis. Encephalitis denotes inflammation of the brain itself, whereas myelitis refers to inflammation of the spinal cord. The terms meningoencephalitis and encephalomyelitis describe more diffuse inflammatory processes. Collections of infective and purulent materials may form within the CNS as abscesses. Brain abscesses may be intraparenchymal, epidural, or subdural, or may be found in intramedullary or epidural spinal locations.

This chapter focuses on the more common acute and subacute CNS infections. Infections of the nervous system with HIV or human T lymphotrophic virus, rabies virus, polio or hepatitis viruses, Borrelia burgdorferi (Lyme disease), Treponema pallidum (syphilis), parasites, Rickettsia, and the chronic and slow infections of the CNS (subacute sclerosing panencephalitis, progressive multifocal leukoencephalopathy, and the prion-mediated spongiform encephalopathies, such as Creutzfeldt-Jakob disease, bovine spongiform encephalopathy, and kuru) are not addressed in detail. Of note, the incidence of neurocysticercosis is on the rise in the United States.

Epidemiology

Bacterial meningitis is a common disease worldwide. Meningococcal meningitis is endemic in parts of Africa, and epidemics commonly occur in other countries, including the United States. A variety of other pathogens are also causative. The overall incidence of bacterial meningitis in the United States is 5 to 10 cases per 100,000 people per year. Men are affected more often than women. In the United States, approximately 80% of cases are caused by either Streptococcus pneumoniae or Neisseria meningitidis. In regions where vaccination is common, the epidemiology of bacterial meningitis has substantially changed. The incidence of bacterial meningitis increases in late winter and early spring, but the disease may occur at any time of the year.

Because most cases are unreported, the actual incidence of viral meningitis is unknown. It is estimated to affect 11 to 27 individuals per 100,000 people. A prominent increase of cases is seen in summer months, which is concurrent with seasonal predominance of the enterovirus group of the picornaviruses.

The same organisms responsible for viral meningitis may also be associated with encephalitis. Encephalitis is, however, far less common, and the ratio of cases of meningitis to encephalitis varies according to the specific pathogen. Arbovirus infection is transmitted by an insect vector, although clinical disease develops in only a small percentage of the people bitten. Before 1999, approximately 19,000 cases of encephalitis were hospitalized in the United States annually. Since then, there has been a rapid increase because of the emergence of
West Nile virus (WNV). In 2003, more than 8000 additional individuals were hospitalized because of WNV alone. \(^\text{25,26}\)

Approximately 2000 cases of brain abscess occur in the United States annually. \(^\text{27}\) Although CNS abscesses may occur at any age and any time of year, they are more commonly seen in men than women. \(^\text{26,29}\) CNS abscesses are associated with local contiguous and remote systemic infections, intravenous (IV) drug use, neurologic surgery, and cranial trauma. Brain abscess secondary to otitis media most often occurs in pediatric or older adult populations. When associated with sinusitis, it most often arises among young adults. Increasingly, CNS abscesses are seen in the immunocompromised population, particularly those with HIV infection, and among bone marrow and solid organ transplant recipients. However, antimicrobial prophylaxis of immunosuppressed patients and more aggressive treatment of otitis and sinusitis have decreased the overall incidence to 0.9 per 100,000 person-years. \(^\text{27}\)

### PRINCIPLES OF DISEASE

#### Etiology

**Meningitis**

Meningeal inflammation may be caused by a variety of disease processes, but the infectious etiologies predominate. Among the bacterial etiologies, *Streptococcus pneumoniae* remains the predominant pathogen in adult patients, followed by *N. meningitidis* and *Listeria monocytogenes*. \(^\text{20,31}\) *N. meningitidis* is the predominant organism in adults younger than 45 years. Five major serogroups cause most meningococcal disease worldwide (A, B, C, Y, and W-135). Serogroup A accounts for the majority of serogroups cause most meningococcal disease worldwide (A, B, C, Y, and W-135). Serogroup A accounts for the majority of meningococcal meningitis in developing nations. \(^\text{32}\) Serogroup distribution for invasive disease has changed markedly in the United States, with B, C, and Y now most commonly responsible. \(^\text{33-36}\) These pathogens account for the bulk of cases in nontraumatic meningitis, although virtually any organism can be encountered, particularly among patients who are elderly, alcoholic, and immunosuppressed and those who have cancer. Interestingly, higher case fatality has been observed in *N. meningitidis* outbreaks versus sporadic cases, likely due to increased virulence of outbreak related strains. \(^\text{37}\) Causes of aseptic meningitis, which simply defined is all cases with negative bacterial CSF cultures, are listed in Box 107-1. \(^\text{38}\)

Meningeal infection may also occur in association with a dural leak secondary to neurosurgery or neurotrauma. *S. pneumoniae, Staphylococcus aureus, Pseudomonas aeruginosa,* and coliform bacteria are seen most commonly in this population. Viral meningitis may likewise be caused by a variety of etiologic agents. \(^\text{39}\) Enteroviruses are statistically encountered most commonly. \(^\text{40}\) Unfortunately, precise definition of the etiologic agent is often impossible. Fungal and parasitic meningitides are additional concerns, particularly among immunocompromised patients. \(^\text{18,19}\)

Noninfectious meningitides include drug-induced meningitis, carcinomatous meningitis, CNS involvement in serum sickness, vasculitis, systemic lupus erythematosus, Behçet’s disease, sarcoidosis, and others. The differentiation of noninfectious from infectious etiologies can often be perplexing.

**Encephalitis**

Arboviruses and herpes simplex virus (HSV), a human herpes virus (HHV), are the most common causes of epidemic and sporadic cases of encephalitis, respectively. Children are the most vulnerable to infection with these viruses, although adults are also commonly affected. Epidemics of viral encephalitis have been attributed to a wide variety of viral agents. WNV, a flavivirus, first infected humans in the New York City area and rapidly spread to 47 states by 2003. \(^\text{19,41}\) Varicella, herpes zoster, HHV 6 and 7, and Epstein-Barr virus have been increasingly reported to be the cause of encephalitis in immunocompetent hosts. \(^\text{42,43}\) Vaccinia encephalitis has been recognized in those receiving vaccination for smallpox. \(^\text{44}\) Postinfectious encephalomyelitis is also induced by a variety of viral pathogens, most commonly by the measles virus. \(^\text{45}\) However, *Mycoplasma pneumoniae* and idiopathic causes are becoming more common in developed countries.

### Central Nervous System Abscess

The etiologies of CNS abscess are multiple and reflect the primary infective process and the immune state of the human host. A variety of mixed pathogens may be responsible for intracranial abscesses. Streptococci, particularly the *Streptococcus milleri* group, have been identified in nearly 50% of brain abscesses. \(^\text{46}\) Anaerobic bacteria, predominantly *Bacteroides* species, are commonly seen when the primary infectious process is chronic otitis media or pulmonary disease. *S. aureus* and *Propionibacterium acnes* are often identified, particularly after cranial penetration from surgery or trauma. \(^\text{37,48}\) The Enterobacteriaceae are an additional common isolate. Opportunistic fungal and parasitic etiologies are often seen in the immunosuppressed, including *Nocardia* species. \(^\text{36,49}\) Culture of epidural and subdural abscesses more often yields a single organism, with streptococci most commonly seen when associated with contiguous spread and *S. aureus* and gram-negative rods most commonly encountered after neurologic trauma. \(^\text{59}\) Etiologic agents in spinal abscess are similarly varied. *S. aureus* is most commonly encountered (Fig. 107-1).

![Figure 107-1. Central nervous system abscess: computed tomography scan of an intraparenchymal abscess (arrows).](image)
I. Infectious causes

1. Viruses
   - Enteroviruses—polio, coxsackie, ECHO virus
   - Herpes group of viruses
   - Herpes simplex virus types 1 and 2
   - Varicella zoster virus
   - Cytomegalovirus
   - Epstein-Barr virus
   - Human herpes virus 6
   - Respiratory viruses
   - Adenovirus
   - Rhino virus
   - Influenza virus types A and B
   - Arboviruses
   - Mumps virus
   - Lymphocytic chorio meningitis
2. Bacteria
   - Partially treated meningitis
   - Parameningeal infection
   - Endocarditis
   - *Mycoplasma pneumoniae*
   - *Mycobacterium tuberculosis*
   - Ehrlichiosis
   - *Borreilla burgdorferi*
   - *Treponema pallidum*
   - *Brucella*
   - Leptospirosis
3. Fungi
   - *Cryptococcus neoformans*
   - *Histoplasma capsulatum*
   - *Coccidioides immitis*
   - *Blastomyces dermatitides*
   - *Candida*
4. Parasites
   - *Toxoplasma gondii*
   - Neurocysticercosis
   - Trichinosis
   - *Naegleria*
   - *Hartmannella*
   - *Bartonella henselae*
5. Rickettsiae
   - Rocky Mountain spotted fever
   - Typhus

II. Noninfectious causes

1. Postinfectious/postvaccinial
   - Rubella
   - Varicella
   - Variola
   - Rabies vaccine
   - Pertussis vaccine
   - Influenza vaccine
   - Vaccinia
   - Yellow fever vaccine
2. Drugs
   - Nonsteroidal anti-inflammatory drugs
   - Trimethoprim-sulfamethoxazole, amoxicillin
   - Muromunab CD3 (OKT3)
   - Azathioprine
   - Intravenous immunoglobulin
   - Isoniazid
   - Intrathecal methotrexate
   - Intrathecal cytosine arabinoside
   - Allopurinol
   - Carbamazepine
   - Sulfasalazine
3. Systemic disease
   - Collagen vascular disorders
   - Systemic lupus erythematosis
   - Wegener's granulomatosis
   - Central nervous system vasculitis
   - Rheumatoid arthritis
   - Kawasaki's disease
   - Sarcomiosis
   - Leptomeningeal cancer
   - Posttransplantation lymphoproliferative disorder
   - Behçet's disease
   - Vogt-Koyabagj syndrome
4. Neoplastic disorders
   - Leukemia
   - Carcinomatous meningitis secondary to primary or secondary tumors of the brain
5. Inflammation of neighboring structures
   - Brain abscess
   - Epidural abscess
6. Miscellaneous
   - Arachnoiditis
   - Migraine
   - Urinary tract infection

**Pathophysiology**

**Bacterial Meningitis**

The pathogenetic sequence in bacterial meningitis has been well characterized.18,19,30,31 The first step is nasopharyngeal colonization and mucosal invasion. Although colonization rates vary, virulent microbes use secretion of immunoglobulin A proteases and induce cilio-stasis of mucosal cells. After penetration occurs by a variety of mechanisms, bacterial intravascular survival occurs because of evasion of the complement pathway. The varying capsular properties of each organism protect the bacteria. The third step occurs when the bacteria cross the blood-brain barrier to enter the CSF. The dural venous sinuses, cribriform plate area, and choroid plexus have all been implicated as potential sites of invasion. Although the mechanism of invasion is not completely understood, host defense mechanisms within the CSF are often ineffective; there are low levels of complement, immunoglobulin, and opsonic activity. Bacterial proliferation then occurs, which stimulates a convergence of leukocytes into the CSF.

Meningeal and subarachnoid space inflammation is also associated with the release of cytokines into the CSF, most notably tumor necrosis factor and interleukins 1 and 6,6,30,32 This results in increased permeability of the blood-brain barrier, cerebral vasculitis, edema, and increased intracranial pressure (ICP). A subsequent decrease in cerebral blood flow leads to cerebral hypoxia. Glucose transport into the CSF is decreased concomitantly with an increased use of glucose by the brain,
bacteria, and leukocytes, which depresses CSF glucose concentrations. The increased permeability leads to increased CSF proteins.

Viral Meningitis and Encephalitis

Viruses enter the human host through the skin (i.e., insect vectors), through the respiratory, gastrointestinal, or urogenital tract, or by receipt of infected blood products or donor organs. Viral replication subsequently occurs outside the CNS, most often followed by hematogenous spread to the CNS. Additional routes into the CNS include retrograde transmission along neuronal axons and direct invasion of the subarachnoid space after infection of the olfactory submucosa.

Fortunately, most systemic viral infections do not result in meningitis or encephalitis. The development and subsequent magnitude of viral infection depend on the virulence of the specific virus, the viral inoculum level, and the state of immunity of the human host. The tropism of the virus for specific CNS cell types also influences the fociality of disease and its manifestations. Particular viruses may preferentially attack cortical, limbic, or spinal neurons, oligodendria, or ependymal cells. An example is the tropism of HSV for the temporal lobes and the development of temporal lobe seizures and behavioral changes in afflicted patients.

Fungal Meningitis

Fungal meningitis probably develops in much the same way as bacterial meningitis, although this has been incompletely studied. Pulmonary exposure followed by hematogenous spread is the primary pathogenetic mechanism in most cases. Immune system defects or immunosuppressive drugs compromise host defense mechanisms, with ensuing development of CNS infection.

Central Nervous System Abscess

Intraparenchymal brain abscesses, subdural empyema, or intracranial or spinal epidural abscesses form by inoculation of the CNS from contiguous spread of organisms from a sinus, middle ear, or dental infection or metastatic seeding from a distant site, usually by hematogenous infection, endocarditis, or osteomyelitis. The primary infection can be identified in 75 to 85% of cases. These conditions may also follow surgery or penetrating cranial trauma, particularly when bone fragments are retained in brain tissue. Otogenic abscesses occur most commonly in the temporal lobe in adults and cerebellum in children, whereas sinogenic abscesses typically occur in frontal areas. Multiple brain abscesses suggest hematogenous spread of organisms, although solitary lesions may also occur. The pulmonary system is the most common source of hematogenous spread.

CLINICAL FEATURES

Symptoms and Signs

Numerous host factors have been implicated in the acquisition of meningitis (Box 107-2). Although these factors alone and in combination increase the risk of meningitis, the disease often occurs in patients with none of these factors.

Many patients with meningitis present with advanced disease; in these patients, the diagnosis of acute meningitis is strongly suspected. The constellation of symptoms that may classically occur in an acute CNS infection consists of fever, headache, photophobia, nuchal rigidity, lethargy, malaise, altered sensorium, seizures, vomiting, and chills. Unfortunately, more subtle presentations are also common. Immunosuppressed and geriatric patients present a diagnostic challenge because the classical signs and symptoms of meningitis may not be present. Although some degree of fever is present in most patients, as are headache and neck stiffness, meningitis should be carefully considered in any immunosuppressed patient with symptoms or signs of infectious disease. Often, the only presenting sign of meningitis in the elderly patient is an alteration of mental status. However, a meta-analysis suggested that the absence of fever, stiff neck, and mental status change excludes meningitis in immunocompetent adults.

The presentation of fungal meningitis can be obscure even in the healthy adult population. Headache, low-grade fever, lassitude, and weight loss may be present but often to such a mild degree that the correct diagnosis is not initially considered. This is also true of tuberculous meningitis, which often has a protracted course and a vague nonspecific presentation consisting of fever, weight loss, night sweats, and malaise, with or without headache and meningismus.

The physical findings in meningitis vary, depending on the host, causative organism, and severity of the illness. Nuchal rigidity or discomfort on flexion of the neck is common. Kernig’s and Brudzinski’s signs are present in approximately 50% of adults. Described in 1882 by Vladimir Kernig, Kernig’s sign is present in the patient if the examiner is unable, because of resistance and hamstring pain, to straighten the patient’s leg passively to a position of full knee extension when the patient is lying supine with the hip flexed to a right angle. Jozef Brudzinski initially described five signs, two of which are currently utilized. The contralateral sign is present if an attempt to flex the hip passively on one side is accompanied by a similar movement of the other leg. The neck sign is present if attempts to flex the neck passively are accompanied by flexion of the hips. The absence of jolt accentuation of headache with this maneuver may be useful in obviating the need for lumbar puncture (LP) in a patient with low suspicion for meningitis. Deep tendon reflexes may be increased, and ophthalmoplegia may be present, especially of the lateral rectus muscles.
The systemic findings may include an obvious source of infection such as sinusitis, otitis media, mastoiditis, pneumonia, or urinary tract infection. Various manifestations of endocarditis may be present. Arthritis may be seen with *N. meningitidis* and occasionally with other bacteria.57 Petechiae and cutaneous hemorrhages are widely reported with meningococemia but also occur with Hib, pneumococcal organisms, *L. monocytogenes*, and echovirus infections, in addition to staphylococcal endocarditis.57 Endotoxic shock with vascular collapse often develops in severe meningococcal disease, but shock may be present in the advanced stages of any bacterial meningitis. Any determination of a serious systemic infection should encourage rather than dissuade the clinician from considering the possibility of a concomitant CNS infection.

Patients with encephalitis may also have symptoms of meningeal irritation. An alteration of consciousness occurs in virtually all patients. Fever, headache, and a change of personality are also usually present.60 Hallucinations and bizarre behavior may precede motor, reflex, and other neurologic manifestations by several days, occasionally prompting an initial diagnosis of a psychiatric disorder. Because focal neurologic deficits and seizures occur much more commonly with encephalitis than meningitis, there may also be diagnostic confusion with a brain abscess. Distinguishing the etiologic agent in encephalitis is clinically difficult, although HSV encephalitis results in a higher incidence of dysphasia and seizures.59 In some patients, WNV produces a myelitis that affects the anterior horn cells of the spinal column, resulting in a flaccid paralysis with a clear sensorium, similar to findings in polio or Guillain-Barré syndrome.41

Patients with intracranial abscess may be indistinguishable from those with meningitis or encephalitis. Most patients with intraparenchymal abscess have a subacute course of illness, with symptoms progressing during the course of 2 or more weeks. However, nuchal rigidity and fever are present in fewer than 50% of cases. Focal neurologic deficits are present in most of these patients. A large number of patients exhibit papilledema, which is a rare finding in meningitis. An abrupt neurologic deterioration that results from uncal herniation or rupture into the ventricular system may occur.

Patients with a subdural or epidural abscess most often have headache, fever, and focal signs, although more subtle presentations are common. Most of the patients with spinal abscess typically present with spinal pain and other symptoms and signs of cord compression but not necessarily with fever.60

**Complications**

**Bacterial Meningitis**

The immediate complications of bacterial meningitis include coma (with loss of protective airway reflexes), seizures, cerebral edema, vasomotor collapse, disseminated intravascular coagulation, respiratory arrest, dehydration, syndrome of inappropriate secretion of antidiuretic hormone, pericardial effusion, and death (Box 107-3).20 Various delayed complications include multiple seizures, focal paralysis, subdural effusions, hydrocephalus, intellectual deficits, sensorineural hearing loss, ataxia, blindness, bilateral adrenal hemorrhage (Waterhouse-Friderichsen syndrome), peripheral gangrene, and death.20

The case fatality rate for pneumococcal meningitis averages 20 to 25%, with higher fatality rates occurring in patients with serious underlying or concomitant disease or advanced age.61,62 The prognosis is related to the degree of neurologic impairment on presentation. Overall, 20 to 30% of the survivors of pneumococcal meningitis have some residual neurologic deficit.57 The case fatality rate for *Listeria* meningitis may be as high as 40%.31

With the advent of antibiotic therapy, the mortality from meningococcal meningitis has markedly decreased to less than 20%, but it remains substantially higher in elderly patients or in those who also have meningococemia.62 Although most of the complications and sequelae are less common than with pneumococcal disease, the incidence of Waterhouse-Friderichsen syndrome is dramatically higher when meningococcal meningitis is present.57 The overall mortality rate in community-acquired gram-negative meningitis has been less than 20% since the introduction of the third-generation cephalosporins.18

**Viral Meningitis**

With rare exceptions, the overall prognosis for complete recovery from viral meningitis is excellent. Various complications related to the systemic effects of the particular virus include orchitis, parotitis, pancreatitis, and various dermatoses. Usually all of these complications resolve without sequelae.59

**Viral Encephalitis**

The outcomes in viral encephalitis are dependent on the infecting agent. Encephalitis caused by Japanese encephalitis virus, Eastern equine virus, and St. Louis encephalitis virus is severe, with high mortality rates and virtually universal neurologic sequelae among survivors.63 WNV produces encephalitis in only 0.5% of those infected, yet it resulted in 120 deaths in 2003.29 Western equine virus and California encephalitis virus cause milder infections, and death is rare. The incidence of neurologic sequelae is highly variable and appears to depend on both the host and the infecting agent.53,64

The mortality rate from HSV encephalitis before the use of acyclovir was 60 to 70%. Acyclovir treatment has reduced the mortality rate to approximately 30%.42 Common sequelae observed among survivors include seizure disorders, motor deficits, and changes in mentation.
Tuberculous Meningitis

Death from tuberculous meningitis in the adult age group ranges from 10 to 50% of cases, with the incidence directly proportional to the patient’s age and the duration of symptoms before presentation. Focal ischemic stroke may result from the associated cerebral vasculitis. In advanced disease, up to 25% of patients may require some neurosurgical procedure for obstruction (ventriculoperitoneal shunt or drainage). In most patients some neurologic deficit develops, but severe long-term sequelae among survivors are unusual.

Fungal Meningitis

Common CNS complications with fungal meningitis include abscesses, papilledema, neurologic deficits, seizures, bone invasion, and fluid collections. Direct invasion of the optic nerve results in ocular abnormalities in up to 40% of patients with cryptococcal meningitis. The mortality rate is high but variable and is related to the timeliness of diagnosis, underlying illness, and therapeutic regimens.

Central Nervous System Abscess

With the early diagnosis afforded by the use of the cranial computed tomography (CT) scan; appropriate antimicrobial therapy; and combined management approaches with surgery, aspiration, and medical therapy, the mortality rate from brain abscess has declined dramatically from approximately 50% to less than 20%. Seizure disorder is the most common sequela of intracranial abscess, occurring in 80% of patients. Other neurologic sequelae of intracranial abscesses, including focal motor or sensory deficits or changes in mentation, are common. Complications of spinal abscess primarily result from cord compression, including paraparesis, motor and sensory deficits, and bowel and bladder dysfunction. Generalized spread of CNS infection and death may also occur.

**DIAGNOSTIC STRATEGIES**

**Lumbar Puncture**

**General Considerations**

Because the consequences of missing a CNS infection are devastating, CNS infection must be presumed to be present until excluded. The possibility of the diagnosis of meningitis mandates LP, unless the procedure is contraindicated by the presence of infection in the skin or soft tissues at the puncture site or the likelihood of brain herniation. Adherence to this principle prevents a delay in diagnosis, which substantially increases the morbidity and mortality of the disease. Some patients have clinically obvious bacterial meningitis, and CSF examination serves primarily to help identify the organism, thereby facilitating the appropriate treatment. Most patients, however, present more of a diagnostic problem, and analysis of the CSF fluid constitutes the critical step in the elucidation of the presence of CNS infection.

**Increased Intracranial Pressure**

In most patients with bacterial meningitis, LP may be safely performed without antecedent neuroimaging studies. As this may not be the case in other brain pathologies, in many circumstances it is advisable to obtain a CT scan of the head before performing an LP. These indications must be carefully weighed against the patient's condition, the probability of meningitis, and the availability of the CT or magnetic resonance imaging (MRI) scan.

It has been conventionally asserted that an LP in the presence of increased ICP may be harmful or fatal to the patient. Although data to address this concern are limited, the presence of focal neurologic signs does appear to be associated with a dramatic increase in complications from LP. These patients may deteriorate precipitously during or after the procedure.

Patients with a markedly depressed sensorium that precludes careful neurologic examination or those with a focal neurologic deficit, papilledema, seizures, or evidence of head trauma must be considered to be at risk for a herniation syndrome that may be exacerbated by an LP. If the presentation is an acute, fulminating, febrile illness and bacterial meningitis is the concerning diagnosis, early initiation of antimicrobial therapy is mandatory because of the association of prognosis and time to treatment. The algorithmic alternatives are therefore (1) immediate LP followed by initiation of antibiotic treatment before obtaining the results or (2) initiation of antibiotic treatment followed by a cranial CT scan and then an LP. The latter choice of empirical treatment with antibiotics is now the routine in many institutions, although in some cases a third option could be considered: antibiotics and no LP despite an unremarkable CT scan. This reflects the efficacy of current methodologies of identification of causative organisms by means other than bacteriologic cultures. The controversy emerging regarding not performing LP despite a lack of CT scan findings is based on some reviews and case reports. These describe a fulminant herniation syndrome temporally related to LP in patients with normal CT scans. Increased ICP may not be reliably detected using CT. Clinical signs of increased ICP, rapid change in consciousness, and recent seizures were identified as risk factors predicting deterioration despite a normal CT scan. The risks of ongoing empirical treatment with antibiotics without additional information from CSF analysis appears to be low, as the yield from blood cultures and other diagnostic techniques such as PCR is relatively high. Therefore, this risk may be less than the risks of performing LP in certain very high-risk patients.

Cerebrospinal Fluid Analysis

**Opening Pressure**

The normal CSF pressure in an adult varies from 50 to 200 mm H2O. This value applies only to patients in the lateral recumbent position and may increase substantially when the patient is in the sitting position. The pressure is often elevated in bacterial, tuberculous, and fungal meningitides and a variety of noninfectious processes. Pressure may be falsely elevated when the patient is tense or obese or has marked muscle contraction.

**Collection of Fluid**

At least three sterile tubes each containing at least 1 to 1.5 mL of CSF should be obtained and numbered in sequence. A fourth tube may be desirable should later studies such as viral cultures or a Venereal Disease Research Laboratories (VDRL) test for syphilis become necessary. The fluid should be sent to the laboratory for immediate analysis of turbidity, xanthochromia, glucose, protein, cell count and differential, Gram’s stain, bacterial culture, and antigen testing (Table 107-1). In certain cases, an India ink stain, bacteriologic stain for acid-fast bacilli, or VDRL test should be obtained. When only a small amount of fluid can be obtained, the most important studies...
are the cell count with differential, Gram’s stain, and bacterial cultures. Ideally, the cell count should be performed on both the first and third or fourth tubes to help differentiate true CSF pleocytosis from contamination of the specimen by a traumatic LP.

**Turbidity**

The CSF should be assessed immediately for turbidity or cloudiness by the person performing the LP. Because normal CSF is completely clear and colorless and should be indistinguishable from water, any degree of turbidity is pathologic. Leukocytosis is the most common cause of CSF turbidity; counts greater than 200 cells/mm³ usually cause clinically detectable changes in CSF clarity.²⁴

**Cell Count and Differential**

Normal adult CSF contains no more than 5 leukocytes/mm³ with at most one granulocyte (polymorphonuclear [PMN] leukocyte)³⁷,⁷⁴,⁷⁵; therefore, the presence of more than one PMN or a total cell count of more than 5 cells/mm³ should be considered evidence of CNS infection. In addition, the presence of any eosinophil in the CSF is abnormal, although occasionally basophils may be seen in the absence of disease.²⁴ Pretreatment with a few doses of antibiotics, although possibly diminishing the yield of Gram’s staining and cultures, should not affect the CSF cell counts in meningitis.¹⁸,³⁰,⁶⁷,⁷⁷

The cell counts in bacterial meningitis are usually markedly elevated, sometimes exceeding 10,000 cells/mm³, and demonstrate a dramatic granulocytic shift.²⁷ In general, counts exceed 500 cells/mm³, with a preponderance of PMN leukocytes. However, the initial CSF analysis exhibits lymphocytosis (lymphocyte count >50%) in 6 to 13% of all cases of bacterial meningitis. When only the patients with bacterial meningitis with fewer than 1000 cells/mm³ are considered, 24 to 32% have a predominance of lymphocytes.⁸,⁷⁹ In addition, the same population of patients often has only a mild disturbance of CSF glucose and protein levels. In well-established viral meningitis and encephalitis, counts are usually less than 500 cells/mm³, with nearly 100% of the cells being mononuclear.⁴⁶ Early (<48 hours) presentations may reveal significant PMN pleocytosis and hence be indistinguishable from presentations in early bacterial meningitis.⁸⁰

Similarly, normal cell counts and differentials, although reassuring, do not absolutely exclude bacterial meningitis.⁷⁸ Any patient thought to have a clinical syndrome compatible with meningitis requires hospital admission with frequent reevaluation, repeated LP, and antimicrobial therapy. In some patients who have symptoms or signs of meningitis and have a normal initial CSF analysis, CSF pleocytosis may develop within 24 hours; the causative organism may be cultured from the original “normal” CSF.

Brain abscess and parameningeal infections, such as subdural empyema or epidural abscesses, usually display CSF cell counts and differentials similar to those of viral meningitis and encephalitis, although the CSF may also be normal.

A traumatic LP is suggested by the presence of a clot in one of the tubes or the clearing of the CSF and a decreasing red blood cell (RBC) count from tubes one to three. In the presence of a traumatic LP, one may estimate the true degree of CSF white blood cell (WBC) pleocytosis with the formula given in Equation 107-1:²⁴

\[
\text{True CSF WBC} = \text{measured CSF WBC} - \left( \frac{\text{CSF RBC} \times \text{blood WBC}}{\text{blood RBC}} \right)
\]

Alternatively, when peripheral cell counts are normal, the CSF from a traumatic LP should contain about 1 WBC per 700 RBCs.

**Gram’s Stain**

A properly performed Gram’s stain of a centrifuged specimen of CSF identifies the causative organism approximately 80% of the time in cases of bacterial meningitis.⁷⁶ Gram’s stain characteristics of the most commonly encountered organisms are described in Table 107-2. The yield from this procedure is diminished by 20 to 30% when there has been prior treatment with antibiotics.¹⁶ Misidentification of gram-positive organisms as gram-negative is also known to occur more commonly among pretreated patients because organisms with damaged walls stain unpredictably.

<tr>
<td>CSF-to-serum glucose ratio</td>
<td>0.6:1</td>
<td>Depressed in pyogenic meningitis or hyperglycemia; lag time if glucose given IV</td>
</tr>
</tbody>
</table>
When a traumatic LP has occurred, the CSF protein can be elevated, which may result from any cause of meningitis, subarachnoid hemorrhage, CNS vasculitis, syphilis, viral encephalitis, neoplasms, and demyelination syndromes. A greatly elevated CSF protein level (>1000 mg/dL) in the presence of a relatively benign clinical presentation should suggest fungal disease.

### Xanthochromia

**Xanthochromia** refers to the yellowish discoloration of the supernatant of a centrifuged CSF specimen. Xanthochromia is abnormal and results from the lysis of RBCs and release of the breakdown pigments oxyhemoglobin, bilirubin, and methemoglobin into the CSF. This process normally begins within 2 hours, and pigments may persist up to 30 days; therefore, early analysis of the LP specimen is essential. If a traumatic tap has introduced enough plasma to raise the CSF protein level to 150 mg/dL or more, blood pigments may cause xanthochromia. If the CSF protein level is less than 150 mg/dL, however, and systemic hypercarotenemia does not exist, xanthochromia of a centrifuged CSF specimen should suggest that subarachnoid hemorrhage has occurred.

### Glucose

When the serum glucose is normal, the CSF glucose is usually between 50 and 80 mg/dL. The CSF glucose is normally in a ratio of 0.6:1 to the serum glucose, except with marked systemic hyperglycemia, when the ratio is closer to 0.4:1. Therefore, a CSF-to-serum glucose ratio of less than 0.5 in normoglycemic subjects or 0.3 in hyperglycemic subjects is abnormal and may represent the impaired glucose transport mechanisms and increased CNS glucose use associated with pyogenic meningitis. Mild decreases in the CSF glucose level may occur with certain viral and parameningeal processes. However, bacterial or fungal meningitis should be presumed to be the cause of low CSF glucose, termed hypoglycorrhachia, until each is clearly excluded. If the serum glucose level has increased rapidly—for example, after IV administration of 50% dextrose in water—equilibration in the CSF may take up to 4 hours, and therefore the interpretation of CSF-to-serum glucose ratios may be unreliable.

### Protein

The normal CSF protein level in adults ranges from 15 to 45 mg/dL. An elevated CSF protein, usually higher than 150 mg/dL, commonly occurs with acute bacterial meningitis. When a traumatic LP has occurred, the CSF protein can be corrected for the presence of blood by subtracting 1 mg/dL of protein for each 1000 RBCs. Elevated CSF protein concentrations can result from any cause of meningitis, subarachnoid hemorrhage, CNS vasculitis, syphilis, viral encephalitis, neoplasms, and demyelination syndromes. A greatly elevated CSF protein level (>1000 mg/dL) in the presence of a relatively benign clinical presentation should suggest fungal disease.

### India Ink Preparation

India ink staining of the CSF should be performed when a diagnosis of cryptococcal meningitis is being considered. The demonstration of budding organisms (Fig. 107-2) is virtually diagnostic for cryptococcal disease but occurs in only one third of the cases. A more definitive diagnostic test is the cryptococcal antigen.

### Lactic Acid

Although nonspecific, elevations in CSF lactic acid concentrations (>35 mg/dL) are potentially indicative of bacterial meningitis, and lactate may rise prior to the decline in glucose. Normal lactate levels (<35 mg/dL) are usually seen in patients with viral meningitides.

### Antigen Detection

Counterimmunoelectrophoresis (CIE), latex agglutination, and coagglutination are methods of detecting specific antigens. These tests are particularly useful in patients receiving antibiotic treatment before CSF sampling because the tests depend on the presence of only an antigen and not viable organisms.

The CIE techniques that are performed for the most common bacterial pathogens demonstrate high sensitivity and specificity for bacterial antigens, particularly when performed on CSF, blood, and urine simultaneously. Latex agglutination techniques are, however, more rapid and sensitive and are replacing the use of CIE in many facilities. Although reported results vary, the sensitivities of antigen tests are 50 to 90% for *Neisseria* organisms, 50 to 100% for *S. pneumoniae*, and approximately 80% for *H. influenzae*. A specific agglutination test for cryptococcal antigen is also highly sensitive (90%) and specific. Cultures are always indicated because a negative antigen test does not exclude the possibility of any particular bacterial or fungal etiology.

Antigen and antibody testing is also being used to identify viral and atypical pathogens. These have particular utility in HSV encephalitis. Enzyme-linked immunosorbent assays can detect HSV antibody production. Unfortunately, the appearance of antibody in CSF occurs too late to aid in any therapeutic decision analysis. PCR amplification and the identification of HSV DNA have demonstrated a sensitivity of 95 to 100%
and a specificity of 100% early in the disease and have markedly decreased the need for diagnostic brain biopsy in this disorder.

PCR has improved the diagnosis of tuberculous meningitis, with a sensitivity of 80 to 85% and a specificity of 97 to 100% and is superior to standard techniques. PCR has additionally been shown to be superior in identifying bacteria, enteroviruses, and other viral etiologies in both immunocompromised and immunocompetent patients.

Reported sensitivities of detection in CSF by PCR for \( N. meningitidis \), \( H. influenzae \), and \( S. pneumoniae \) are 88, 100, and 92%, respectively, with nearly 100% specificity. The sensitivities of bacteriologic culture are much lower, especially for \( N. meningitidis \) at 37 to 55% and \( H. influenzae \) at 50%. In addition, PCR assays have nearly tripled the yield of viral culture in identifying the etiologic agent. In studies of enteroviral meningitis, sensitivities and specificities for PCR ranged from 86 to 100% and 92 to 100%, respectively. PCR has been shown to be at least as sensitive as culture technique in detecting cryptococcal meningitis. Quantitative PCR may be of benefit in monitoring response to therapy in some forms of severe disease.

The growing availability of these molecular techniques does not, however, suggest that they should be routinely employed. Most cases of acute bacterial meningitis are readily diagnosed and treated on the basis of the standard Gram’s stain and culture. PCR should be reserved for less clear presentations, patients pretreated with antibiotics, and cases in which concern exists for tuberculous, cryptococcal, and treatable viral CNS infections.

**Bacteriologic Cultures**

Although results are not available for emergency management, bacteriologic cultures of CSF should be performed. Bacterial culture yields are significantly decreased in patients pretreated with antibiotics. Viral cultures may also be indicated.

**Other Tests**

A variety of additional, nonspecific tests of CSF have been advocated. These include measuring CSF lactate dehydrogenase, C-reactive protein, and the limulus lysate test; however, none of these have demonstrated a high degree of clinical usefulness. Likewise, the evaluation of CSF chloride as a diagnostic aid for tuberculous meningitis is no longer clinically relevant.

**Neuroimaging Techniques**

A cranial CT scan or MRI scan is indicated in the evaluation of any patient with presumed CNS infection in whom there is the possibility of an intracranial abscess, intracranial hemorrhage, or mass lesion. In the diagnostic evaluation of acute meningitis, however, a CT scan should not unnecessarily delay LP or antimicrobial therapy. The CT scan may also show hypodense lesions in the temporal lobes in patients with HSV encephalitis, although an MRI scan reveals this abnormality much earlier in the disease process. A contrast-enhanced cranial CT scan or MRI scan is invaluable in the diagnosis of a CNS abscess. MRI scanning is also helpful in the evaluation of other infectious and noninfectious encephalitides.

**Additional Investigations**

As with other infectious diseases, the complete blood count with differential is a nonspecific adjunct in the diagnostic evaluation of a patient suspected to have a CNS infection. The peripheral cell counts are often normal in the presence of significant disease and may even be depressed, particularly in elderly or immunosuppressed persons. A “normal” leukocyte count and differential should not dissuade the emergency physician from performing a diagnostic LP, obtaining a CT scan, or otherwise pursuing the diagnosis of a CNS infection. Serum C-reactive protein is nonspecific, but a negative test result is potentially helpful. Procalcitonin is emerging as a promising serum marker in infectious disease; however, there is not convincing evidence at this point to advocate its use to attempt to rule out bacterial meningitis.

Even when antimicrobial therapy has already been administered, two or three blood cultures should be obtained for all patients who are being evaluated for a CNS infection. The blood cultures can improve the identification of the causative organisms, especially with pneumococcus and to a lesser degree meningococcus. Although blood cultures are not immediately useful in the acute diagnosis of meningitis in the emergency department, they may be of considerable clinical importance later in the management of the disease. The cultures are helpful in identifying a causative organism in only a small minority of cases of brain abscesses.

As many as 50% of patients with pneumococcal meningitis also have evidence of pneumonia on an initial chest radiographic study. This association occurs in fewer than 10% of the cases of meningitis caused by Hib and \( N. meningitidis \) and in approximately 20% of cases of meningitis caused by other organisms. The identification of a pulmonary infection on chest radiography may assist in identification of causative organisms and appropriate antimicrobial therapy in approximately 10% of cases of brain abscesses.

Other ancillary investigations such as echocardiography, cultures of other body fluids, and bone scans may be undertaken as necessary to evaluate coexistent or complicated disease. Serum electrolytes, glucose, urea nitrogen, and creatinine levels should be measured to facilitate the interpretation of the CSF glucose level and to establish the level of renal function and the state of electrolyte balance. Although organism-specific abnormalities are uncommon, hyponatremia has been associated with tuberculous meningitis.

A number of characteristic but not pathognomonic electroencephalographic abnormalities have been associated with HSV type 1 encephalitis. The presence of focal or lateralized electroencephalographic abnormalities in the presence of an encephalitis syndrome should be considered strong evidence supporting a diagnosis of HSV encephalitis.

### Differential Considerations

Patients with meningitis may have symptoms and signs ranging from mild headache with fever to frank coma and shock. To facilitate the discussion of diagnosis and treatment, meningitis may be divided into three clinical syndromes: acute meningitis, subacute meningitis, and chronic meningitis.

Acute meningitis encompasses patients with obvious signs and symptoms of meningitis who are evaluated in less than 24 hours after the onset of their symptoms and who rapidly deteriorate. In many of these patients the diagnosis of meningitis is not in doubt, and the crucial step is to initiate antimicrobial therapy immediately. The most likely pathogens in this syndrome are \( S. pneumoniae \) and \( N. meningitidis \). Although \( H. influenzae \) has been reported in this context, it is not commonly implicated in the adult population.

In the syndrome of subacute meningitis, the symptoms and signs causing the patient to seek care have developed during a period of 1 to 7 days. This syndrome includes virtually all cases of viral meningitis, along with most of the bacterial and...
some of the fungal etiologies.\textsuperscript{18,19} The differential diagnosis depends on the symptoms and signs at presentation. Among elderly and immunosuppressed individuals, a change in the patient’s mental status may be the only presenting sign in meningitis. Even when a fever is present, the patient’s change in mental status may be misattributed to another disease outside the CNS, such as pneumonia or urinary tract infection; neck stiffness may be misattributed to degenerative joint disease. The elderly patient is at high risk for meningitis and, rather than constituting a diagnostic endpoint, the identification of an infection outside the CNS in such a patient is a clear indication for LP because of the risk of bacteremic seeding by the involved organisms.

The differential diagnosis of encephalitis and brain abscess occurs in the context of the subacute meningitis syndrome. Brain abscesses should be considered, especially if fever is minimal or absent or if there are focal neurologic findings. The presence of fever, altered sensorium, headache, seizures, and personality change is consistent with encephalitis. In addition, diagnoses such as subdural empyema, brain tumor, subarachnoid hemorrhage, subdural hematoma, and traumatic intracranial hemorrhage should be considered. In these circumstances a cranial CT scan should be obtained before performing an LP.

The spectrum of chronic meningitis includes some of the viral meningitides as well as meningitis caused by tubercle bacilli, syphilis, and fungi. Many of the patients in this group have had symptoms for at least 1 week before presentation and generally have a prolonged indolent course marked by difficult and changing diagnoses and multiple therapies.\textsuperscript{16,17} Prediction rules have been both derived and validated and have not yet diffused into widespread practice, likely due to limitations in the models, shifts in the epidemiology of the causative organisms, and relatively small sample sizes.\textsuperscript{103–105}

\section*{MANAGEMENT}

\subsection*{Assessment and Stabilization}

Septic shock, hypoxemia, seizures, cerebral edema, and hypotension resulting from dehydration require aggressive management. When possible, a thorough history should be obtained from the patient, family members, or ambulance personnel with particular emphasis on preexisting conditions that may complicate the patient’s disease. Examples include recent neurosurgery, trauma, a history of leukopenia, immunocompromise, or diabetes mellitus.

Hypotension or shock should be treated as indicated with isotonic crystalloid infusion, high-flow oxygen, and pressors. IV dextrose may be required for hypoglycemia secondary to depletion of glycogen stores. Alcoholic or nutritionally compromised patients should also receive 50 to 100 mg of IV thiamine. In cases of moderate to severe hypotension, central venous pressure monitoring should be initiated and used as a guide for additional IV fluids or vasopressors. In children, after volume resuscitation there does not appear to be evidence to restrict fluids and appropriate maintenance fluids should be instituted.\textsuperscript{106}

Active airway management with endotracheal intubation may be required, particularly in cases of coma, recurrent seizures, or severe accompanying pulmonary infection. Cardiac monitoring may also be necessary, particularly in elderly patients, those with known coronary disease, and those with an altered mental status. Seizures are a particularly prominent component of the clinical presentation in patients with a brain abscess but may also occur with any CNS infection, especially when an underlying seizure disorder is present.

If acute cerebral edema or an elevated ICP is present, it should be managed by immediate intubation and adequate ventilation. Osmotic agents such as mannitol or diuretics such as furosemide may be used, but caution should be exercised if shock or uncontrolled hypotension is present. If diuretics or osmotic agents are administered, the emergency physician must ensure that the patient does not become volume depleted and hypotensive.

\subsection*{Definitive Therapy}

\subsection*{Bacterial Meningitis}

Therapy for bacterial meningitis requires antibiotics that penetrate the blood-brain barrier and achieve adequate CSF concentrations, are bactericidal against the offending organism in vivo, and maintain adequate tissue levels to treat the infection effectively.

Until the pathogenetic organism is identified, broad-spectrum coverage of the most common pathogens is necessary (Table 107-3). Many authorities recommend cefotaxime or ceftriaxone, plus vancomycin to cover potentially resistant organisms.\textsuperscript{107} High-dose ampicillin is also added if concern exists about \textit{Listeria}.\textsuperscript{107} In patients allergic to penicillin and cephalosporins, meropenem or chloramphenicol plus vancomycin may be effective while awaiting the outcome of desensitization techniques.\textsuperscript{107}

After the pathogen is identified, more targeted therapy can be instituted. It is prudent to refer to a current antimicrobial reference to guide therapy in all instances, given rapid changes in etiologic spectrum, drug resistance, and available agents. Duration of treatment varies, and in certain situations (namely epidemics in sub-Saharan Africa), long-acting chloramphenicol or ceftriaxone is effective.\textsuperscript{108}

Corticosteroid treatment is additionally recommended in adult acute bacterial meningitis. Animal studies demonstrate the salutary effects of the administration of corticosteroids in experimental pneumococcal meningitis, including reduced brain edema, CSF pressure, and CSF lactate levels.\textsuperscript{109} Earlier resolution of the clinical and CSF stigmata of meningitis and a decrease in long-term hearing loss are observed in infants and children given dexamethasone with cefuroxime or ceftriaxone compared with those receiving the antibiotic alone, particularly when \textit{H. influenzae} is the offending agent.\textsuperscript{110,111} In adult bacterial meningitis, an absolute risk reduction of 10% for unfavorable outcome is seen when dexamethasone is given either 15 minutes before or concomitantly with antibiotics and continued for 4 days at 6-hour intervals.\textsuperscript{112} This benefit was greatest in those with \textit{S. pneumoniae}. Subgroup analyses for different causative organisms did not establish a benefit; however, the study was not designed with adequate power to detect improved outcomes. In addition, amoxicillin and penicillin were the most commonly used initial therapy, due to the process of health care delivery in Europe at the time of that study in which nearly all patients were seen initially in an office-based practice. A recent randomized controlled trial did not demonstrate a benefit of adjuvant dexamethasone in adult patients, even when only those with \textit{S. pneumoniae} were included in a secondary analysis.\textsuperscript{113} In the current era of initial empiric parenteral therapy, rising \(\beta\)-lactam resistance, the possibility of the decreased CSF penetration of vancomycin after dexamethasone treatment, and shifts in the likely causative organisms secondary to vaccination campaigns, the true effectiveness of dexamethasone is unclear. The most recent meta-analysis suggests a benefit, but the included studies suffer from one or more of the aforementioned limitations.\textsuperscript{114}

*Ceftriaxone or cefotaxime.*

*bSome experts would add rifampin if dexamethasone is also given.*

*cIn infants and children, vancomycin alone is reasonable unless Gram's stains reveal the presence of gram-negative bacilli.*

In pediatric meningitis, the evidence that adjunctive dexamethasone is helpful is less compelling. Invasive Hib and pneumococcal infections have drastically been reduced by vaccination.223 A randomized trial of dexamethasone in childhood meningitis in sub-Saharan Africa did not demonstrate a benefit.116 Current recommendations are organism specific, which presents a major limitation as recommendations are to begin empiric therapy prior to laboratory results in suspicious cases. For Hib, “dexamethasone may be beneficial for treatment of infants and children with Hib meningitis to diminish the risk of neurologic sequelae, including hearing loss, if given before or concurrently with the first dose of antimicrobial agent(s).” There probably is no benefit if dexamethasone is given more than 1 hour after antimicrobial agent(s).116 For *S. pneumoniae*, “for infants and children 6 weeks of age and older, adjunctive therapy with dexamethasone may be considered after weighing the potential benefits and possible risks. Experts do not agree on a recommendation to use corticosteroids in pneumococcal meningitis; data are not sufficient to demonstrate a clear benefit in children. If used, dexamethasone should be given before or concurrently with the first dose of the antimicrobial agent.” The implication for frontline physicians caring for children is that unless the causative organism is known prior to antibiotic treatment, there is probably little role for adjunctive dexamethasone in children.

Viral Meningitis

No specific agents are available for treating most types of viral meningitis. Investigational agents in development may reduce symptoms in enterovirus meningitis; however, with the exception of HSV meningitis, the viral meningitides contracted in the United States are generally characterized by a short, benign, self-limited course followed by a complete recovery. The primary therapeutic consideration in cases of viral meningitis is therefore the validity of the diagnosis. Early cases of viral meningitis may be indistinguishable from bacterial meningitis, and this confusion may not be resolved by CSF analysis; therefore, when any doubt exists about the veracity of the diagnosis, appropriate cultures should be obtained and the patient admitted to the hospital. Antimicrobial therapy for presumed bacterial meningitis may be initiated on the basis of the clinical presentation or may be withheld pending the outcome of close clinical observation and repeated LP in 8 to 12 hours.

Viral Encephalitis

Specific therapy for meningoencephalitis from HHV is available. Acyclovir remains the current choice and is capable of substantially improving the patient’s outcome. When the diagnosis of herpes meningoencephalitis is suspected or established, IV acyclovir should be administered in a dose of 10 mg/kg every 8 hours.81 Ganciclovir, foscarnet, and cidofovir are also effective in HHV infections, and pleconaril has been effective in enteroviral disease. Additional antiviral treatments are in development.

Tuberculous Meningitis

Early chemotherapeutic intervention in acute tuberculous meningitis improves the patient’s prognosis. A strong clinical suggestion of this disease is an adequate indication to begin antituberculous therapy. A standard treatment regimen consists of isoniazid, rifampin, pyrazinamide, and ethambutol or streptomycin. Corticosteroids have also been shown to decrease secondary complications.
The treatment of fungal meningitis is complex. Four agents are commonly used: amphotericin B, fluconazole, miconazole, and fluconazole. Of these, amphotericin B, either alone or in combination with fluconazole, is the most commonly recommended initial therapeutic regimen. These diseases are rarely acutely life-threatening but rather are slowly progressive. Prolonged therapy, often with multiple agents, is necessary. The initiation of antifungal therapy is rarely indicated in the emergency department.

Central Nervous System Abscess

The treatment of cerebral abscess is complex, and neurosurgical consultation is indicated. The location, size, and number of abscesses influence the choice of medical management, surgical excision, aspiration, or a combination of these modalities. In general, small multiple abscesses are more appropriately treated medically, whereas large, surgically accessible lesions should be excised. Empirical antimicrobial therapy before identification of specific organisms by aspiration or surgical excision should be guided by the principles of CSF penetration and the coverage of likely pathogens. Otogenic and sinogenic abscesses are often treated with cefotaxime or ceftriaxone plus metronidazole. Abscesses with traumatic or neurosurgical causes should have antimicrobial coverage for *S. aureus* or methicillin-resistant *S. aureus*. Patients at high risk for tuberculous, fungal, or parasitic abscesses should also receive coverage for the suspected etiologic agent. Corticosteroids should be reserved specifically for managing any attendant cerebral edema; in other circumstances, steroid use is associated with increased mortality. In cases where the etiology is bacterial endocarditis, valve replacement is often required.

Chemoprophylaxis

Among household contacts, the incidence of transmission of meningococcus is approximately 5%; therefore, it is recommended that household contacts of bacteriologically confirmed cases receive rifampin (adults, 600 mg; children older than 1 month, 10 mg/kg; children younger than 1 month, 5 mg/kg) orally every 12 hours for a total of four doses. In addition, these contacts should be advised to watch for fever, sore throat, rash, or any symptoms of meningitis. They should be hospitalized with appropriate IV antimicrobial therapy if there are signs that active meningococcal disease is developing because rifampin is ineffective against invasive meningococcal disease. Intimate, nonhousehold contacts who have had mucosal exposure to the patient’s oral secretions should also receive rifampin prophylaxis. Health care workers are not at increased risk for the disease and do not require prophylaxis unless they have had direct mucosal contact with the patient’s secretions, as might occur during mouth-to-mouth resuscitation, endotracheal intubation, or nasotracheal suctioning. Ciprofloxacin 500 mg by mouth (adults only) and ceftriaxone 250 mg intramuscularly (125 mg intramuscularly for children younger than 15 years) provide single-dose alternatives.

There is no indication for chemoprophylaxis in pneumococcal meningitis. Rifampin prophylaxis for the contacts of patients with Hib meningitis is recommended for nonpregnant household contacts when there are children younger than 4 years of age in the household (adults, 600 mg by mouth; children, 20 mg/kg by mouth daily for 4 days).

Immunoprophylaxis

A quadrivalent vaccine based on the polysaccharide capsule and conferring protection against group A, C, Y, and W-135 meningococci has been in routine use by the U.S. military since the 1980s. However, the capsular polysaccharide vaccines used to immunize adults are neither immunogenic nor protective in children younger than 2 years because of poor antibody response. In addition, no licensed vaccine is currently available against the serogroup B meningococcus. The serogroup B capsular polysaccharide has proved to be poorly immunogenic in both adults and children. The sequence variation of the surface proteins and cross-reactivity of the group B polysaccharide with human tissues have further impeded efforts to develop a successful vaccine. Efforts to enhance the immunogenicity and protective efficacy of meningococcal vaccines have focused on using conjugate methods that link polysaccharides and carrier proteins. Serogroup C and serogroup C + Y conjugate vaccines have been developed and utilized effectively. Current recommendations for the quadrivalent vaccine are evolving. The vaccine is recommended in established meningococcal epidemics and for travelers to countries where meningococcal disease is currently epidemic. Elective vaccination of college freshmen has been recommended by the Advisory Committee on Immunization Practices (ACIP) in the United States and public health authorities in the United Kingdom. The United Kingdom has also implemented universal childhood immunization with a group C conjugate vaccine.

The development of effective pneumococcal vaccines has been hampered by the large number of serotypes of the organism. A small number of serotypes, however, is responsible for most clinical pneumococcal disease, and a 23-valent vaccine effective against many of these principal serotypes has been developed. The recommendations for this polyvalent pneumococcal vaccine are targeted primarily at prevention of pneumonia, despite a potential beneficial effect for meningitis. A single dose of the vaccine should be considered for elderly or debilitated patients, especially those with pulmonary disease, and for patients with impaired splenic function, splenectomy, or sickle cell anemia. A heptavalent conjugated pneumococcal vaccine has also been developed and is recommended for universal childhood immunization by the ACIP. A conjugate vaccine effective against Hib has been developed for use in the pediatric, but not adult, population. It appears to be approximately 90% protective and has a very low incidence of adverse reactions. Modern childhood immunization against Hib has raised the average age of patients afflicted with *Haemophilus* meningitis to 25 years and decreased the incidence of meningitis of any etiology by 55%. Vaccination is also available to confer immune protection against Japanese encephalitis virus, and it is recommended for people performing extensive outdoor activities or spending more than 30 days in endemic areas during transmission seasons. The reported protective efficacy of the vaccine is approximately 90%. Although there is no current human vaccine for the WNV, vaccines for nonhuman mammals have been developed.

**DISPOSITION**

With the exception of viral meningitis, all but the most chronic CNS infections require initial inpatient evaluation and treatment. Bed rest, analgesics, and the institution of appropriate IV antimicrobials are indicated.
Some patients with suspected viral meningitides merit hospitalization. These include patients with more severe disease, immunocompromise, suspicion of HSV meningitis, or potential nonviral causes. Some authorities manage patients with classical presentations of viral meningitis as outpatients and ensure close follow-up within 24 hours. Others admit all patients until the more serious causes, such as early bacterial meningitis or encephalitis, can be excluded with certainty.

KEY CONCEPTS

- CNS infection should be considered in all patients with headache, neck stiffness, fever, altered sensorium, or diffuse or focal neurologic findings.
- Lumbar puncture with sampling of CSF is the only reliable method of assessing the presence or absence of meningitis. In the absence of contraindications, any suspicion of meningitis mandates performance of LP.
- Early initiation of antimicrobial therapy is mandatory in any case of suspected acute CNS infection. Antibiotic administration must not be delayed for CSF analysis or performance of neuroimaging studies.
- Antibiotic chemoprophylaxis should be assured for close contacts of patients with meningitis resulting from *N. meningitidis* or *H. influenzae*. Single-dose and multiple-dose regimens are available.
- Vaccination against *N. meningitidis* is recommended for certain at-risk populations but does not afford protection against serogroup B infection.
- Concomitant CNS infection should be strongly considered in any patient with another severe systemic infection, such as urinary tract infection or pneumonia.

The references for this chapter can be found online by accessing the accompanying Expert Consult website.
In the 1800s, Morel introduced the term dementia praecox to describe a progressive deterioration of mental functioning and behavior with onset in adolescence to early adult life. In 1911 Bleuler detailed the specifics of this disorder, which he termed schizophrenia, or “split-mindedness.” Early treatments for schizophrenia included ice water immersion, the use of barbiturates or insulin to induce prolonged narcosis or coma, seizure induction with pentylenetetrazol, electroconvulsive therapy, and frontal leukotomy. The effectiveness of these treatments was marginal at best, and until more recent times most schizophrenic patients were relegated to lifelong institutionalization.

Modern-era pharmacotherapy of schizophrenia, principally with chlorpromazine and haloperidol, began in the early 1950s. This treatment proved so successful that, by the 1960s, most psychiatrists believed that schizophrenia could be successfully managed in the outpatient setting. In 1965, the Community Mental Health Centers Act initiated the release of medicated schizophrenic patients into the community. Unfortunately, inadequate family support, the unavailability of jobs and low-cost housing, and the lack of funding for social services and outpatient psychiatric care left these individuals isolated without the tools needed for resocialization. This situation has improved little since that time, and currently 20 to 40% of homeless people in the United States have a major mental illness. Emergency departments in the United States and worldwide frequently serve as the primary entry point into the mental health care system for many of these individuals.

The etiology of schizophrenia is currently believed to be heterogeneous from interaction of biologic and environmental factors. Studies involving adopted twins whose biologic parents have schizophrenia demonstrate a strong genetic basis for the disorder. Although the overall incidence of schizophrenia in the general population is approximately 1%, it is approximately 10% in first-degree biologic relatives of individuals with the disorder. With regard to the pathophysiology of schizophrenia, dopaminergic, serotonergic, cholinergic, and glutamatergic systems have been implicated. Schizophrenia is also postulated to be a neurodevelopmental disorder resulting from the influence of environmental factors on genetically predisposed individuals. Disruptions in fetal brain development, caused by perinatal hypoxia, poor nutrition, infection, and other insults, may set the stage for subsequent development of schizophrenia. New imaging techniques have documented structural brain abnormalities, most of which appear to be developmental rather than degenerative in nature. Evidence supports the existence of a progressive continuum of psychotic illness, beginning with unipolar depression, progressing to bipolar illness, schizoaffective psychoses, and finally to schizophrenia.

Overt signs of schizophrenia usually become manifest during adolescence or early adult life. Many patients describe a childhood marked by few interpersonal relationships and a withdrawn, eccentric personality.

The development of schizophrenia involves three phases. The premorbid phase is characterized by the development of “negative” symptoms with deterioration in personal, social, and intellectual functioning. Patients progressively withdraw from social interactions and neglect personal appearance and hygiene, which negatively impacts their work, school, and home life.

The active phase is usually precipitated by a stressful event with development of “positive” symptoms such as active delusions, hallucinations, and bizarre behavior. Patients may become agitated or exhibit a hypervigilant withdrawal state characterized by rocking or staring. It is during this phase that they are most likely to be brought to the emergency department by family, friends, coworkers, or the police.

In the residual phase patients are left with impaired social and cognitive ability, marked by bizarre ideation, delusions, peculiar behavior, poor personal hygiene, and social isolation. Most schizophrenic patients require a sheltered environment to function adequately. Despite a wide spectrum of severity, the general course for most patients is one of gradual deterioration with periodic episodes of psychotic decompensation.

The diagnostic criteria for schizophrenia are outlined in the fourth edition of the Diagnostic and Statistical Manual of Mental Disorders (DSM-IV-TR) (Box 108-1). The patient must exhibit two or more of the following symptoms: delusions,
hallucinations, disorganized speech, grossly disorganized or catatonic behavior, and negative symptoms such as flattening of affect, poverty of speech, or inability to perform goal-directed activities. (2) There must be a sharp deterioration from the patient’s prior level of functioning (work, school, self-care, or interpersonal relations), and there must be continuous signs of disturbance for at least 6 months. (3) The diagnoses of schizoaffective and mood disorders with psychotic features must be excluded. (4) In evaluating these patients, emergency physicians must exclude myriad medical conditions that can mimic or cause psychotic symptoms (Boxes 108-2 and 108-3).

### Delusions

The DSM-IV defines delusions as “erroneous beliefs that usually involve a misinterpretation of perceptions or experiences.” Delusions seen with schizophrenia are most often persecutory, religious, or somatic.

### Hallucinations

A hallucination is a sensory experience that exists only in the mind of the person experiencing it. Hallucinations associated with schizophrenia may be auditory, visual, olfactory, gustatory, or tactile. Auditory hallucinations (hearing voices) that are pejorative or threatening are especially common.

### Disorganized Speech

Patients with schizophrenia experience loosening of associations, with thoughts shifting randomly from one topic to another without a logical connection. Their speech often shows lack of content. Neologisms (nonsense words invented by the patient) and perseverations (frequently repeated words or phrases) are common. Occasionally, the patient's speech may be so severely disorganized that it is totally incoherent, termed word salad.

### Grossly Disorganized or Catatonic Behavior

Schizophrenic patients have difficulty formulating and producing goal-directed behavior. They are often found wandering about, disheveled, malnourished, talking to themselves, and exhibiting unpredictable agitation. It is this behavior that usually prompts family members, friends, or the police to bring them to the emergency department. Patients exhibiting catatonia appear to be completely unaware of their environment, maintain a rigid posture, and resist efforts to be moved.
Medical Disorders That May Cause Acute Psychosis

Metabolic disorders
- Hypercalcemia
- Hypercarbia
- Hypoglycemia
- Hyponatremia
- Hypoxia

Inflammatory disorders
- Sarcoidosis
- Systemic lupus erythematosus
- Temporal (giant cell) arteritis

Organ failure
- Hepatic encephalopathy
- Uremia

Neurologic disorders
- Alzheimer’s disease
- Cerebrovascular disease
- Encephalitis (including HIV)
- Encephalopathies
- Epilepsy
- Huntington’s disease
- Multiple sclerosis
- Neoplasms
- Normal-pressure hydrocephalus
- Parkinson’s disease
- Pick’s disease
- Wilson’s disease

Endocrine disorders
- Addison’s disease
- Cushing’s disease
- Panhypopituitarism
- Parathyroid disease
- Postpartum psychosis
- Recurrent menstrual psychosis
- Sydenham’s chorea
- Thyroid disease

Deficiency states
- Niacin
- Thiamine
- Vitamin B₁₂ and folate

Negative Symptoms

Three negative symptoms—flattening of affect, alogia, and avolition—account for a significant degree of the morbidity associated with schizophrenia. Patients with a flattened affect exhibit little facial expressiveness, eye contact, or body language. Alogia, or poverty of speech, is manifested by brief, laconic, empty replies to questioning. Avolition is characterized by an inability to initiate and persist in goal-directed activities. Caution should be used in evoking negative symptoms to support a diagnosis of schizophrenia, because similar symptoms may be found in patients with severe depression, chronic environmental understimulation, and treatment with neuroleptic medications.

DIFFERENTIAL CONSIDERATIONS

Medical Disorders

Certain medications and medical disorders may affect thought processes, causing patients to exhibit abnormal behavior (see Boxes 108-2 and 108-3). This behavior may range from mild personality changes to apparent acute psychosis, even in the absence of an underlying psychiatric disorder. Factors that should alert one to a medical disorder include (1) history of substance abuse or a medical disorder requiring medication, (2) patient’s age greater than 35 years without previous evidence of psychiatric disease, (3) recent fluctuation in behavioral symptoms, (4) hallucinations that are primarily visual in nature, (5) presence of lethargy, (6) abnormal vital signs, and (7) poor performance on cognitive function testing, particularly orientation to time, place, and person. These and other factors may be helpful in differentiating functional (psychiatric) from organic (medical) causes of abnormal behavior and can be organized for easy recall into the mnemonic MADFOCS (Table 108-1).

Although the classic textbook differentiation between functional and organic causes of abnormal behavior is straightforward, the evaluation of individual patients may be difficult. A patient with underlying psychiatric disease may develop a medical disorder, which may worsen the patient’s behavioral symptoms and further cloud the distinction between functional and organic disease. This evaluation is particularly difficult in the emergency department when previous medical or psychiatric history is not available, the patient is uncooperative, and the time frame to make a disposition is brief. When the clinical differentiation between functional and organic disease is unclear on the basis of available information, a patient should be thoroughly evaluated to exclude a toxicologic or medical disorder.

Psychiatric Disorders

A previously undiagnosed patient who presents with an acute functional psychosis may ultimately be given one of several psychiatric diagnoses. A brief psychotic disorder involves the sudden onset of psychotic symptoms in response to major stress and lasts from several days to 1 month. Patients with schizophreniform disorder have similar symptoms that last longer than 1 month but less than 6 months. While one third of
individuals initially given the diagnosis of schizophreniform disorder recover within 6 months, the other two thirds retain their symptoms and are diagnosed as having schizophrenia. Patients with mood disorders may develop psychotic symptoms. If these symptoms are present only during periods of mood disturbance, the diagnosis of mood disorder with psychotic features is applied; if they persist longer than 2 weeks in the absence of prominent mood symptoms, the diagnosis of schizoaffective disorder is made. Patients with personality disorders may occasionally develop brief psychotic episodes under stress.

Ganser’s syndrome is a symptom complex considered to be emotional in origin in which the patient may appear to have amnesia, hallucinations, or alterations in consciousness, usually in association with physical complaints. An individual with Ganser’s syndrome may have psychotic symptoms for no apparent gain except to assume the role of the psychiatric patient.

Persons with a delusional disorder experience nonbizarre delusions that may dominate their lives. They may believe that famous people are in love with them (erotomanic type), that they have extraordinary powers with a special relationship to a deity or a famous person (grandiose type), that their sexual partner is unfaithful (jealous type), that they are being malevolently treated in some way (persecutory type), or that they have some physical defect or general medical condition (somatic type). Although patients with somatic delusions may experience tactile or olfactory hallucinations related to the delusional theme (e.g., the sensation of being infested with insects), the other features associated with schizophrenia are not present.

### MANAGEMENT

#### General Approach

Patients with thought disorders may be agitated and hyperactive, may be withdrawn but hypervigilant, or may complain of somatic delusions. In addition, they may have paranoid ideation, may be angry they have been brought to the emergency department against their will, or may be frightened because they have been confronted by the police, restrained, and isolated. The presence of such patients in the emergency department may be disconcerting to staff because these patients are often irrational, erratic, and unpredictable in their behavior. Although emergency personnel must remain calm, empathetic, and reassuring in their interactions with patients exhibiting a thought disorder, they must also take steps to ensure staff safety whenever dealing with patients at risk for sudden violence. Such patients include those who have manifested violent behavior before coming to the emergency department, those who physically or verbally threaten staff, and those who demonstrate an escalating level of agitation despite verbal attempts to calm them.

Each patient should have a complete history and physical examination performed, including a detailed mental status evaluation, to rule out an organic brain syndrome. Valuable information can be obtained from family members, friends, coworkers, neighbors, paramedical personnel, police, or previous medical records (see Table 108-1).

The most important step in evaluating a patient with a suspected thought disorder is the assessment of the patient’s thought processes through the initial interview. The goals are to establish a positive physician-patient relationship, to make a correct diagnosis, and to gather information necessary to render an optimal disposition. The interview should be conducted in a quiet, comfortable room with adequate privacy. The examiner should be sitting, and if possible the interview should proceed to completion without interruption. If the patient is believed to be potentially dangerous but is not in need of immediate restraint, the interview should take place in an open area with security personnel nearby.

The emergency physician should begin with an introduction and should express the desire to be “of help” to the patient. The interview should begin with open-ended questions designed to assess the patient’s complaint and understanding of the current circumstances. Good opening questions include “Do you understand why you have been brought here

|**Table 108-1** Factors in Differentiating Organic and Functional Psychosis: MADFOCS |
|---|---|---|
|**ORGANIC**|**FUNCTIONAL**|
|Memory deficits|Recent impairment|Remote impairment|
|Activity|Psychomotor retardation|Repetitive activity|
|Distortions|Tremor|Posturing|
|Feelings|Ataxia|Rocking|
|Orientation|Visual hallucinations|Auditory hallucinations|

...
today?"; “You seem to be upset. Can you tell me why?”; and “Do you have any idea why you might be having these symptoms?” The patient’s appearance, body language, affect, and speech should be observed during the responses to these questions.

A brief mental status examination should be performed. It may be initiated in a nonthreatening manner by stating, “I am now going to ask you a few questions to see how well you are concentrating.” The patient should first be asked questions regarding orientation to time, place, and person, as this is the most sensitive test for differentiating organic from functional disease. Patients who are disoriented should have a detailed medical evaluation to exclude the presence of an organic brain syndrome. Patients who are oriented should be assessed for attention, memory, intellectual functioning, and judgment in an attempt to determine their specific diagnosis, their potential for danger to themselves or others, and their degree of dysfunction and ability to care for themselves in the outpatient setting.

Rapid Tranquilization

When psychotic patients exhibit behavior that is violent or so disorganized and uncooperative that clinical evaluation is impossible, the temporary use of physical restraints is indicated while rapid tranquilization is initiated (see Chapter 189). The technique of rapid tranquilization involves serial doses of a high-potency antipsychotic agent until target symptoms, such as agitation and excessive psychomotor activity, are improved. The goal is to facilitate cooperation of the patient without causing unnecessary sedation, which would inhibit the patient’s ability to communicate. If the patient is willing, an oral concentrate is preferred as it implies consent and can take effect almost as quickly as IM administration. Haloperidol (Haldol), a butyrophenone, is widely used for rapid tranquilization in the United States.25–27 The initial dose is 5 to 10 mg intramuscularly or intravenously for young to middle-aged patients and 0.5 to 2.0 mg intramuscularly or intravenously for elderly patients. Although rapid tranquilization with haloperidol quickly reduces tension, anxiety, and hyperactivity, delusions and hallucinations may not resolve for several weeks. In 2007, the U.S. Food and Drug Administration (FDA) released a non–black box warning about sudden death with the use of haloperidol in large doses or through the IV route. Droperidol (Inapsine), another butyrophenone, has also been extensively used for this indication in doses from 2.5 to 5.0 mg intramuscularly or intravenously.28,29 Compared with haloperidol, droperidol has a faster onset and shorter duration of action and causes slightly more sedation. The FDA black box warning was published in 2001 because of reports of a potential association between droperidol and prolonged QT interval, torsades de pointes, and sudden death.30 Despite subsequent studies supporting both the efficacy and safety of droperidol, the FDA warning has resulted in a significant decrease of its use in clinical practice.31,32 Neuroleptics should not be used for pregnant or lactating females, phenylcyclidine overdose, or anticholinergic drug-induced psychosis. In addition, they should not be used as the sole agent to manage agitation in patients with drug or alcohol withdrawal.

Newer atypical antipsychotic agents appear to have a broader spectrum of response with fewer side effects than the typical agents. These medications are available in tablet form and should be considered for patients who consent to oral medication. However, oral administration of a pharmacologic agent during an acute episode of agitation and psychosis is usually impossible. Ziprasidone (Geodon), aripiprazole (Abilify), and olanzapine (Zyprexa) are newer atypical antipsychotics currently approved in the United States for IM injection.33 For ziprasidone, the initial dose is 20 mg intramuscularly and can be repeated every 4 hours. It has been shown to be as or more effective than haloperidol for sedation and with fewer extrapyramidal side effects, but it has not yet been widely used in the emergency department setting.34,35

Benzodiazepines are effective in managing agitation in patients who have alcohol or sedative-hypnotic withdrawal, cocaine intoxication, or a contraindication to neuroleptic use. Benzodiazepines are helpful adjuncts to neuroleptic medication in providing rapid tranquilization, particularly in patients exhibiting combativeness or severe agitation. Lorazepam (Ativan), 1 to 2 mg, is frequently mixed with haloperidol, 5 mg, in the same syringe and administered intramuscularly or intravenously for this purpose.32 Benzodiazepines have also been shown to mitigate catatonic signs in schizophrenic patients.36 Disadvantages of benzodiazepines are the need for repeat dosing and close monitoring for potential respiratory depression with large doses.37

Outpatient Management

The outpatient treatment of schizophrenia involves maintenance therapy using neuroleptic agents, family counseling, and social rehabilitation. Emergency physicians rarely prescribe outpatient neuroleptic medications but should be familiar with complications associated with their long-term use. Box 108-4 lists the most common neuroleptic medications currently used in the United States.38–44 The mechanism of action is related to the blockade of dopamine receptors in the central nervous system, particularly dopamine D2 receptors in the basal ganglia and limbic portions of the forebrain. The earlier, less potent drugs, of which chlorpromazine...
is the prototype, cause more pronounced sedation, orthostatic hypotension, and cardiovascular toxicity. This is the result of a combination of anticholinergic, antihistaminic, and anti-alpha-adrenergic effects. More potent agents (e.g., haloperidol) are safer, especially in older patients, because of their relative lack of these adverse effects. However, these more potent drugs are associated with a higher incidence of extrapyramidal symptoms, such as dystonias, akathisia, akinesia, and rigidity.

The high frequency of severe adverse reactions, poor compliance by patients, and the large number of patients with symptoms refractory to traditional antipsychotic agents prompted the development of new alternative agents. These “atypical” neuroleptic agents block serotonin to a greater extent than dopamine, resulting in a low incidence of extrapyramidal side effects. Clozapine is particularly effective in patients who have not responded to other antipsychotic drugs. However, clozapine is expensive, has a side effect profile similar to that of the low-potency antipsychotic agents, and causes agranulocytosis in approximately 1% of patients. It is recommended only for the treatment of patients with refractory psychosis. Olanzapine, quetiapine, and the newest agent, aripiprazole, are similar to clozapine but have fewer side effects and less risk of agranulocytosis. Risperidone, another newer neuroleptic agent with improved effects on negative symptoms, has been found to be superior to haloperidol in several short-term trials. The most recent FDA-approved drug (2006), paliperidone (Invega), is the active metabolite of risperidone. Unfortunately, the expense and unavailability of these newer antipsychotic agents limit their utility for treating acute psychosis in the emergency department. Ziprasidone, risperidone, and quetiapine have been associated with QT interval prolongation similar to that seen with droperidol and haloperidol but have not yet been found to be associated with sudden cardiac death.

Because of the high incidence of extrapyramidal symptoms in patients treated with high-potency neuroleptics, it is common practice to administer antiparkinsonian drugs (e.g., benztropine, procyclidine, trihexyphenidyl) at the same time, either to treat the adverse effects or to prevent them. Prophylactic treatment is most useful in patients with a history of extrapyramidal symptoms, those receiving high doses of high-potency antipsychotic agents, and those in whom the occurrence of these symptoms is likely to increase the risk of noncompliance.

Noncompliance with antipsychotic medication remains a leading cause of psychiatric hospitalization. Patients with recurrent psychotic relapses caused by noncompliance are candidates for treatment with long-acting injectable antipsychotic drugs, usually given every 2 weeks. Three such agents available in the United States are fluphenazine, risperidone, and haloperidol decanoate.

Complications of Neuroleptic Drug Therapy

Dystonia

Acute dystonia, the most common adverse effect seen with neuroleptic agents, occurs in 1 to 5% of patients. This reaction is caused by a disruption of the dopaminergic-cholinergic balance in the nigrostriatal pathways of the basal ganglia, resulting in cholinergic dominance. Dystonic reactions, which can occur at any point during long-term therapy and up to 48 hours after administration of neuroleptics in the emergency department, involve the sudden onset of involuntary contraction of the muscles of the face, neck, or back. The patient may have protrusion of the tongue (buccolingual crisis), deviation of the head to one side (acute torticollis), sustained upward deviation of the eyes (oculogyric crisis), extreme arching of the back (opisthotonos), and rarely laryngospasm. These symptoms tend to fluctuate, decreasing with voluntary activity and increasing under emotional stress, which occasionally misleads emergency physicians to believe they are factitious.

Dystonic reactions should be treated with IM or IV benztropine (Cogentin) 1 to 2 mg, or diphenhydramine (Benadryl), 25 to 50 mg, which usually results in immediate reversal of symptoms. Patients should receive oral therapy with the same medication for 48 to 72 hours to prevent recurrent symptoms.

Akathisia

Akathisia is a state of motor restlessness characterized by a physical need to be moving constantly. It occurs most often in middle-aged patients during the first few months of therapy. Patients are usually pacing the room and expressing a sense of inner tension that is not relieved by activity. If asked, they do not want to be constantly moving but feel physically compelled to do so. This reaction can easily be mistaken for a decompensating psychosis, leading to a vicious circle in which more medication is given to treat a side effect caused by the same drug. This misdiagnosis can be avoided by carefully evaluating the patient for the exacerbation of positive psychotic symptoms, which are not increased by akathisia. Akathisia is treated with beta-blockers (e.g., propranolol, 30–60 mg/day) and anticholinergic drugs (e.g., benztropine, 1 mg twice to four times daily). A new potential agent for the treatment of akathisia is glycine, a nonessential amino acid that stimulates glutamatergic neurotransmission. In addition, if possible, the dosage of the antipsychotic agent should be lowered or replaced with another drug.

Pseudoparkinsonism and Akinesia

A clinical picture can occur that may be indistinguishable from Parkinson’s disease, particularly in elderly patients during the first month of therapy. Treatment with anticholinergic agents (e.g., benztropine) or antiparkinsonian drugs is usually effective. Akinesia, which is characterized by immobility, withdrawal, and lack of motivation, may be mistaken for a postpsychotic depression. It is responsive to antiparkinsonian drugs, but symptoms usually resolve gradually over time.

Tardive Dyskinesia

Tardive dyskinesia usually appears after several years of neuroleptic drug treatment and is characterized by involuntary movements, especially of the face and tongue, that are described as writhing, grimacing, and choreoathetoid in nature. The earliest manifestation is often a curling or twisting movement of the tongue. The onset of these symptoms can be falsely attributed to psychological factors because they intensify under emotional stress, fatigue, and voluntary activity, and disappear with sleep.

The reported prevalence of tardive dyskinesia ranges from 0.5 to 70%, with a mean value of 24%. The incidence of the disorder appears to be directly related to the duration of treatment, total cumulative dosage, evidence of preexisting brain damage, and age of the patient. It is more common in elderly women and patients with associated mood disorders. For patients with mild symptoms, discontinuing or lowering the dosage of antipsychotic agents, switching to a newer atypical neuroleptic agent, and cotreatment with benzodiazepines may reverse the symptoms. Patients with moderate to severe symp-
Orthostatic Hypotension

All the antipsychotic agents can cause orthostatic hypotension, an effect related to alpha-adrenergic blockade. This complication is less common with the more potent agents (e.g., haloperidol). Typically, episodes are mild in severity and brief in duration. Symptomatic patients should be treated with oxygen, Trendelenburg’s position, and IV crystalloid fluid administration. Pressor agents (e.g., dopamine) should be used only for severe, symptomatic episodes that fail to respond to the previous measures. Agents with beta-agonist activity (e.g., epinephrine, isoproterenol) are contraindicated in these patients.

Neuroleptic Malignant Syndrome

Neuroleptic malignant syndrome (NMS) is a life-threatening complication of neuroleptic drug treatment that affects 0.5 to 1% of patients. It is seen with both typical and atypical neuroleptic agents and usually occurs in the first few weeks after initiation of treatment, but can also be seen after a recent increase in drug dosage or after parenteral treatment with high doses of neuroleptic agents. Neuroleptic malignant syndrome is characterized by high fever, severe muscle rigidity, altered consciousness, autonomic instability, and elevated serum creatine kinase levels and can be confused with serotonin syndrome. Additional complications can include respiratory failure, gastrointestinal hemorrhage, hepatic and renal failure, coagulopathy, and cardiovascular collapse.

The pathophysiology of NMS is not well understood, but it is thought to be related to dopamine depletion in the central nervous system leading to defective thermoregulation in the hypothalamus. Predisposing factors include exhaustion, dehydration, and the use of long-acting depot neuroleptics. Treatment consists of recognition and discontinuation of the neuroleptic agent, fever reduction, rehydration with IV fluids, and general supportive measures. Dantrolene, a direct-acting muscle relaxant, should be used in severe cases. It can be administered by continuous rapid IV push at a minimum initial dose of 1 mg/kg, repeated until symptoms subside or up to a maximum cumulative dose of 10 mg/kg. For severe symptoms, dopamine agonists such as bromocriptine, levodopa, and amantadine have shown encouraging results. Because of earlier recognition and treatment, mortality rates with NMS have decreased from 30% to less than 10%.

- DISPOSITION

The ultimate disposition of the acutely psychotic patient depends on the underlying cause of the psychosis, whether the patient is a danger to self or others, and the presence of social support in the community. Hospitalization is indicated for patients experiencing their first psychotic episode, for patients deemed to be a danger to themselves (suicidal) or others (homicidal), for patients who are grossly debilitated, for patients who are moderately debilitated but have no social support system within the community, and for patients with either functional or organic psychosis that does not clear with a brief period of treatment and observation in the emergency department. The decision to hospitalize psychotic patients is complex and imprecise and often must be made in a short period with limited information.

A psychiatric short-procedure unit offers a cost-effective alternative to hospitalization. After stabilization, patients are moved from the emergency department to a separate treatment area, where they are treated for a period of 12 to 24 hours by a small staff of consultants.

The references for this chapter can be found online by accessing the accompanying Expert Consult website.
Happiness and sorrow are common emotions but usually cause no impairment in functioning or threat to life. Mood disorder, by contrast, can significantly impair physical, social, and family functioning and can cause psychological pain, physical pain, and a negative perception of physical health. The term mood disorders replaced the term affective disorders in the fourth edition (2000) of the Diagnostic and Statistical Manual of Mental Disorders (DSM-IV-TR). Mood usually refers to an individual's subjective emotional state, whereas affect normally refers to the individual's emotional state as it appears to an outside observer. Mood disorders refers to a group of psychiatric disorders where pathological moods are the dominant feature. According to DSM-IV-TR, mood disorders are divided into four categories: (1) depressive disorders (unipolar depression), (2) bipolar disorders, (3) mood disorder due to a general medical condition, and (4) substance-induced mood disorder. DSM-IV-TR assigns psychiatric diagnoses to patients by assessing specific observable and measurable symptoms and signs and applying straightforward operational criteria. Research regarding the neurobiology of mood disorders and genetics may ultimately permit classification of mood disorders by specific, genetically predisposed pathophysiologic derangements.

### EPIDEMIOLOGY

Psychiatric problems account for at least 5.4% of all emergency department (ED) visits, and the rate of psychiatric-related visits has increased 15% since 1992. The World Health Organization ranks major depression as one of the most prevalent and disabling diseases in the world, and the lifetime prevalence of major depressive disorders in the United States is 16.2%.Depressed patients also have associated anxiety disorders (almost 60%), substance use disorders (24%), and impulse control disorder (30%). Depressed patients with substance abuse comorbidity have higher ED utilization than patients without such comorbidity. Patients with chronic illness have a much higher prevalence of undiagnosed depression than the general population. The lifetime suicide risk for persons with major untreated depressive illness is 15%. Mood disorders are becoming more common and have increased in every generation born after 1910. The prevalence of bipolar disorders (manic-depressive disorders) is substantially lower than that of major depression. The overall lifetime prevalence of a manic episode is 1.6%.

### PRINCIPLES OF DISEASE

Current neurobiologic concepts provide the basis for various pharmacologic treatments. The psychosocial theories of depression consider the complex interaction of genetics, environment, and experience, providing the basis for understanding the various psychotherapeutic approaches to treatment.

**Neurotransmitters**

In the fourth century BCE, Hippocrates believed that the body contained four essential humors: blood, phlegm, yellow bile, and black bile. Harmony in the brain required a harmony of humors. “Disharmony” produced mental illness. In the second century, Galen believed that “melancholia” resulted from an excess of black bile acting on the brain. Such excesses were thought to be caused by noxious stomach vapors, grief, anxiety, excessive wine, and advancing age. Proposed treatments included bloodletting, surgery, special diets, and exercise.

Modern theories regarding the pathophysiology of depression have focused on the three major monoamine systems—serotonin, norepinephrine, and dopamine. Of the three neurotransmitter systems, serotonin has received the most attention. There is very strong evidence of reduced activity of serotonergic neurons in depression as assessed by cerebrospinal fluid and neuroendocrine studies. There are also very strong data demonstrating the role that norepinephrine plays in the etiology of depression. Norepinephrine reuptake inhibitors, such as nortriptyline, have been found to be effective antidepressants. Research over the past several years has increasingly focused on the role of dopamine in the etiology of depression. A number of studies have found a reduction in the synaptic availability of dopamine in patients suffering from depression.

Complex processes in the nervous system cause depression or mania. If the concentrations of neurotransmitters at synaptic sites were the only factors responsible for alleviation of depression, the therapeutic effect of an antidepressant agent would be almost immediate. However, clinical improvement with these agents takes several weeks and is highly individually variable. Emphasis has now shifted to the study of neurobehavioral systems, intricate regulatory mechanisms, development of preferred neural circuits, the effect of environment on phenotype expression, and gene transcriptors.
Cerebral Anatomy

Certain areas of the brain are involved in processes that become abnormal during episodes of depression and mania. Stress activates neurons in the locus ceruleus, resulting in increased alertness, decreased appetite, increased heart rate, increased cortisol production, and other features of a stress response. The response can be dampened by neurons in the cerebral cortex. Prolonged stress, from which escape appears hopeless, may explain the lack of energy and interest that accompany depression.

Serotonergic neurons are located in the brainstem dorsal raphe and project diffusely throughout the brain. The serotonergic system seems to enhance sleep, appetite, libido, and circadian rhythms. Activation decreases aggressive behavior in animal models.

Dopaminergic pathways include the tuberoinfundibular system, originating in the hypothalamus (prolactin secretion); the nigrostriatal system, originating in the substantia nigra (involuntary motor activity); the mesolimbic pathway, originating in the ventral tegmentum; and the mesocortical pathway, originating in the ventral tegmentum. These pathways regulate emotion, pleasure, learning, and reinforcement. The mesocortical pathway extends to frontal cortical regions that regulate complex cognition concentration and motivation.

Endocrine System

The cortical-hypothalamic-pituitary-adrenocortical system is affected in many patients with depression, causing increased levels of plasma cortisol, apparently from an impaired biofeedback loop regulating cortisol. The thyroid axis malfunctions in 5 to 10% of depressed patients. Thyroid-stimulating hormone levels are elevated, and thyroid replacement therapy facilitates treatment in certain patients.

Genetics

Family studies have repeatedly demonstrated a relationship between genetic inheritance and mood disorders. A review of twin studies in unipolar depression estimates that genetics accounts for 30 to 40% of the risk of developing depression, with the rest being attributed to environmental factors. Monozygotic and dizygotic twins have a high concordance rate, 70 and 35%, respectively, for mood disorder. The mechanisms of genetic transmission are still undetermined but may relate to the synthesis, transport, and action of serotonin and other transmitters. The inherited susceptibility to depression may manifest only during severe stress or serious illness.

Psychosocial Theories

The complex neural mechanism that regulates mood responds to and is modified by each person’s experience, including events in early childhood, reward and punishment during growth and development, interpersonal relationships, and various kinds of loss. Psychosocial theories of mood disorder form the basis for psychotherapy. Freud noted that personal loss included grief and sadness, but that depression also involved guilt and lowered self-esteem. Freud theorized that suicide in depressed patients is a manifestation of aggression that has been turned against the self in a person otherwise unable to express anger toward loved ones.

cognition, and vegetative function.\textsuperscript{28} The patient must exhibit or experience at least five symptoms for a minimum of 2 weeks.

**Mood Disturbances**

Depressed mood is painful and referred to as being anguished, sad, gloomy, dejected, unhappy, discouraged, or in low spirits. The mood may also involve feelings of anxiety and irritability. The patient’s feelings can be so intensely painful that suicide may be seen as the only way to terminate the agony.

Anhedonia refers to the inability to experience pleasure or interest in formerly pleasurable or satisfying activities. The patient must have actually stopped doing the formerly pleasurable activities, for example, an avid tennis or golf player who gives up playing entirely. Questions can help to elicit loss of interest or pleasure: “When were you last feeling well?”; “When you were feeling well, what kinds of things did you do for enjoyment?”; “Are you doing those things now?”; and “Are you enjoying them?”\textsuperscript{29}

**Disturbances in Psychomotor Activity**

Psychomotor disturbances can take the form of retardation or agitation. Psychomotor retardation includes significant slowing of thought processes and physical activity. The patient is slow to answer questions and moves slowly or not at all. Questioning such patients in the ED may be frustrating when the answers come slowly, in short words or phrases, and are low in volume and lack inflection. The “body language” of depression includes sitting slumped over, arms folded, mouth turned down, and eyes closed or downcast. Such slowing clearly affects the patient’s work, school, or family functioning. Symptoms may be erroneously attributed to worsening dementia in elders. An alternative presentation is psychomotor agitation, in which the patient fidgets, paces, rubs the skin, and is unable to sit still. Other common, almost stereotypical manifestations include hand wringing and tugging at the hair.

**Vegetative Disturbances**

Vegetative symptoms include disturbances in three major areas: sleep, appetite, and sexual function. Depressed patients typically report some form of sleep disorder, such as difficulty falling asleep, middle insomnia, or the classic symptoms of early-morning wakening and inability to fall back to sleep. Some depressed patients may report sleeping 12 to 14 hours a day and inability to arise in the morning. This may be a more common symptom in depressed teenagers. The depressed patient may lose appetite and weight or may gain weight in a short time. Loss of interest in sexual activity and impotence can be considered vegetative symptoms; they may accompany depression or may be part of the anhedonia associated with depressed mood.

**Cognitive Disturbances**

Depressed patients are unable to concentrate or think properly, which can cause significant dysfunction in a job or profession. Thought content is negative, such as recurrent thoughts of guilt, failure, worthlessness, and self-criticism. Suicide may preoccupy the patient’s thinking and may reinforce feelings of helplessness, perpetuating self-reproach. The patient may formulate a definite plan for ending life. Depressed patients must be questioned about suicidal thoughts and plans, which allow them to describe their pain and may provide them with some relief.

Psychosis may accompany severe depression. Hallucinations and delusions are classified as mood congruent or mood incongruent. Mood-congruent delusions reflect the depressed mood. The patient may report, for example, being “already dead” or feeling like “my insides have rotted away.” Hallucinations typically consist of voices saying extremely unpleasant things or punishing the patient for previous wrongs. Mood-incongruent delusions do not reflect the depressed mood as clearly and include the paranoid delusions of being followed and having one’s thoughts controlled by external forces.

**Special Considerations**

**Masked Depression**

Mood disorders may not be clear at presentation. The depressed patient may have only vague physical symptoms, such as weakness, fatigue, headache, or complaints of pain. Patients may not be aware of their depression and are often heavy utilizers of medical care. Such symptoms may be the presenting features of a masked, or hidden, depression. Clues suggesting mood disturbance include the recent onset of a set of unusual behaviors, trouble at work or job loss, marital difficulties, or self-destructive behavior (e.g., substance abuse, sexual promiscuity).

**Children and Adolescents**

A common and overt presentation of depression in an older child or teenager is a suicide attempt. Such patients should be considered depressed and unstable until subsequent assessment differentiates depression from other conditions in these age groups, including transient psychoses, anxiety disorders, high levels of life stress, and substance abuse.

Symptoms of depression in children and adolescents generally follow the same criteria as for adults. Some children are misdiagnosed as having attention deficit disorder, especially if symptoms involve poor concentration, listlessness, agitation, and withdrawal from daily activities. Depression in these age groups is often misunderstood, masked in its presentation, or simply overlooked by friends, parents, teachers, and physicians. Adequate treatment maximizes the child’s potential and minimizes the serious negative impact depression can have on multiple spheres of development.

**Elders**

Depression is common in elders; losses and grief, serious health issues, and loss of autonomy create a setting conducive to depression. The classic symptoms of moderate to severe depression, with or without psychosis, are typically seen. Depressed patients can present with symptoms involving
memory loss, inattention, withdrawal from daily activities, confusion, and lapses in personal and social hygiene that suggest dementia rather than depression. When such symptoms are from depression, the condition is called pseudodementia. Serious depression in elders is a highly treatable, reversible condition. Distinguishing it from dementia is essential for further diagnostic and therapeutic follow-up.

Other Depressive Disorders

Seasonal Affective Disorder

Seasonal affective disorder is not a separate mood disorder but a subclassification of major depressive disorder that is diagnosed when major depression occurs during seasons with less daylight (fall and winter), then either resolves or occasionally changes to manic episodes in seasons with more daylight, for at least 2 consecutive years. Melatonin, a hormone secreted in the brain and produced at high levels in the dark, has been implicated in the etiology of this disorder. Symptoms generally include hypersomnia, anergia, weight gain, and craving for carbohydrates. Phototherapy is an effective and safe treatment for this “winter depression,” and light exposure to the eyes seems to be essential but the exact mechanism of action is still unknown.

Postpartum Depression

Symptoms of depression are common in the postnatal period. Up to 65% of mothers report some depressed mood after childbirth, often called “postpartum blues.” Symptoms are generally mild and transient, although in some patients it may lead to an episode of major depression. Approximately 10% of mothers will experience a full-fledged episode of depression in the postpartum period. The signs and symptoms of postpartum depression are similar to those of a major depressive disorder, but the onset is within four weeks of delivery. Postpartum depression is more common in those who have a history of mood disorder, experience marital conflict, and have limited assistance with infant care. Severe postpartum depression may negatively influence development in the child.

Dysthymic Disorder

Dysthymic disorder is a long-standing, fluctuating, low-grade depression. Some features of a major depressive episode may be present, but marked changes in appetite or psychomotor disturbances are not typically observed. Depressed mood typically begins early in life, and the individual may report having always been depressed. Affected individuals generally are able to carry out their work assignments, but they gain little pleasure from the leisure activities others find enjoyable, such as recreation, time with family, or sexual activity. They typically experience significant impairment in interpersonal functioning.

Bipolar Disorders

Bipolar disorder is lifelong, with episodic exacerbation of symptoms and deterioration of function characteristic by extreme mood swings. Patients with bipolar disorder thus require different forms and intensities of treatment at different times. Bipolar I disorder includes at least one manic episode, and patients have typically had one or more major depressive episodes. Bipolar II disorder involves a hypomanic episode and at least one major depressive episode. A hypomanic episode includes the features of a manic episode without psychosis, marked impairment of function, or the need for hospitalization.

Manic Episode

To be considered manic (Box 109-3), the disturbance must be severe enough to cause psychosis, the need for hospitalization, or marked impairment in functioning. Bipolar disorders are much less common than major depressive disorder. The overall prevalence of a manic episode is 1.6% in both women and men. Patients who are experiencing a manic episode may be gregarious, humorous, and engaging. An alternative presentation is one of belligerence and irritability. Clues to mania include a history of the patient’s behavior immediately before the evaluation and any prior history of bipolar disorder or a history of taking medications almost exclusively prescribed for bipolar disorder, such as lithium. In most cases, the manic patient will be brought to the ED by someone else (e.g., family, police, emergency medical services). They often try to leave as soon as possible, display impaired judgment and impulsivity, and may need to be restrained.

Pressured speech is one of the first clinical signs of mania. The patient keeps talking, with no interruption between thoughts or sentences. The speech may be loud and rapid, with creative, amusing, or trivial and irrelevant content. The patient may tell jokes, use puns, or play other word association games. A hallmark of mania is grandiosity, which involves feelings of inflated self-esteem and great personal importance. The patient may
describe a massive undertaking such as “uniting the world’s churches” or “solving world poverty.”

Manic patients have decreased or no need for sleep and typically report being awake for days during a manic episode. They may be involved in a massive project (e.g., writing a novel), may completely disregard consequences of actions, may have difficulty with spending (e.g., credit cards revoked), and may engage in risky behavior (e.g., sexual liaisons with strangers, risky driving). An accurate history must be obtained from family or others who know the patient’s behavior.

Manic patients may present to the ED as trauma patients, injured by an action reflecting the patient’s grandiosity (e.g., attempting to fly), impulsivity, or belligerence (e.g., fighting, resisting arrest). A manic episode may be punctuated by abrupt periods of tearfulness and profound depression, including suicidal ideation. When depressive and manic features occur concurrently in such a manner, the disorder is termed mixed or bipolar, mixed phase.

**Cyclothymic Disorder**

Cyclothymic disorder is characterized by a life of mood swings of insufficient severity to meet criteria for a bipolar disorder. Persons with this disorder may have a chaotic life, characterized by frequent mood swings, unstable relationships, and uneven school or work performance.

**Mood Disorders Caused by a General Medical Condition**

Certain medical illnesses have a well-known association with mood disorder (Box 109-4). In Parkinson’s disease, electrical stimulation to a certain area of the substantia nigra alleviates symptoms of depression. Stimulation of an area only 2 mm away can cause acute reversible symptoms of depression, such as crying, not wanting to live, and hopelessness. Parkinson’s disease has a well-known association with depression, with up to 40% of patients demonstrating major depression.

Certain malignancies have a well-known association with depression, including pancreatic carcinoma, brain neoplasm, and disseminated malignancy (e.g., lymphoma). Coronary artery disease, myocardial infarction, stroke, end-stage renal disease, acquired immunodeficiency syndrome, several endocrine diseases, and connective tissue disease are also associated with major depressive disorder. After a myocardial infarction, patients with depression experience a 3.5-fold increase in cardiovascular mortality compared with nondepressed patients. Patients with depression appear to be more likely to develop stroke, diabetes, and osteoporosis than those who are not depressed.

Depression related to medical conditions may be different in some respects from primary depression. For instance, the former responds less favorably to antidepressant medication than primary depression. Two significant issues arise in the assessment of patients with depression who have a serious medical illness. First, symptoms of depression must be distinguished from the symptoms and signs associated with serious medical illness (e.g., weight loss, loss of energy, slowing of activity, sleep disturbance, loss of ability to concentrate). Some experts have proposed that alternative criteria for depression caused by general medical condition be substituted for DSM-IV-TR neurovegetative symptoms in patients with serious medical illness such as depressed appearance, social withdrawal, pessimism or self-pity, anhedonia, and nonreactive mood. Second, it is important to determine whether the depression associated with terminal, rapidly progressive, or painful illness should be considered appropriate. Although patients with such diseases may understandably be sad, most do not have major depression. The treatment of major depression in such patients should always be attempted and can greatly improve their quality of life.

**Mood Disorders Caused by Medications or Other Substances**

Certain medications are associated with symptoms of mood disorders (Box 109-5).

Intoxication or chronic heavy use of alcohol, sedatives, hypnotics, anxiolytics, narcotics, and other depressants can cause symptoms of a major depressive episode. Stimulants such as cocaine, phencyclidine, hallucinogens, and amphetamines can cause symptoms of a manic episode. Mood disorder symptoms can also develop during withdrawal. To qualify for this diagnosis, the symptoms must not occur exclusively during a course of delirium, must cause significant distress or impairment of functioning, and must develop within a month of either substance intoxication or withdrawal.

When the mood disorder predates the period of substance abuse or lasts longer than 1 month after the period of abuse, the diagnosis may be an underlying mood disorder, such as a major depressive disorder or bipolar disorder, with a comorbid substance abuse or dependence diagnosis.

Substance abuse is often seen in patients with underlying depressive or bipolar conditions.

**DIAGNOSTIC STRATEGIES**

The initial history and physical examination should focus on the presenting complaints and evaluate the possibility that drug abuse, medications, or a general medical condition may be responsible for the patient’s condition. The diagnosis of a
Adjustment disorders are behavioral or emotional disorders that occur in response to an identifiable stress or stressors. The emotional component can involve sadness, low self-esteem, suicidal behavior, hopelessness, helplessness, or other self-threatening behavior. Acute adjustment disorder occurs within 3 months of the stressor and does not last longer than 6 months. The stressors are typically not as severe as those precipitating bereavement reaction, and the responses are often more maladaptive. The teenager who ends a romantic relationship, for instance, may attempt a drug overdose in response to the stress. In such cases, adjustment disorder is a more likely diagnosis than major depressive episode. The pattern of recurrent maladaptive behavioral responses to stress may be lifelong, but the acute episode should resolve within 6 months.

Borderline personality disorder is characterized by unstable personal relationships, unstable self-image, and inappropriate behaviors. The disorder may include chronic feelings of emptiness, which may be misdiagnosed as depression, or lability of mood, which may be mistaken for mania or hypomania. Borderline patients typically live lives of crisis and constant conflict.

Dementia can be confused with depression. Dementia is characterized by abnormal mental status, including abnormalities in tests of memory, calculation, and judgment. Delirium with waxing and waning sensorium, hallucinations, and delusions may involve disorganization, agitation, and restlessness, which might first be considered features of mania or agitated depression.

Differential considerations for manic symptoms include the manic phase of bipolar disorder, stimulant abuse (e.g., cocaine, amphetamines), hallucinogen abuse, alcohol or sedative withdrawal, delirium, hyperthyroidism, other medical conditions causing agitation, brief reactive psychosis, schizoaffective disorder, and schizophrenia.
**Emergency Department Stabilization**

The creation of a safe and stable environment for the patient must be a first priority in management. The patient with an acute manic episode may be disruptive, refuse medical evaluation, and make repeated attempts to leave the ED. The initial step in treating such a disruptive patient is to offer assistance in reducing their agitation (placing the patient in a single room, recommending medication). At times this approach does not work and the patient may need to be placed in restraints for his or her safety and that of others.

Initiating treatment for a mood disorder is not typically done in the ED. An exception is the acute manic episode (or possibly a severe depressive episode with psychosis) with behavior so extreme that the patient or others are threatened. Such cases may well involve significant hallucinations, delusions, and other features of psychoses. In such cases an antipsychotic agent is often indicated. For years, clinicians have used intramuscular or oral haloperidol with or without lorazepam to calm such patients. A typical regimen for “rapid tranquilization” is an initial dose of 5 mg haloperidol with 2 mg lorazepam intramuscularly and reassessment in 30 to 45 minutes for resolution of “target” symptoms such as agitation. Another 5-mg dose is administered after 30 to 60 minutes as needed for improvement in hallucinations, delusions, agitation, or violent behavior. Most patients respond after one or two doses. Benztpipine (Cogentin), 1 to 2 mg, is often given initially to prevent extrapyramidal symptoms. Droperidol is a popular antipsychotic drug used effectively for agitation but has a black box Food and Drug Administration (FDA) warning about prolongation of QT intervals and torsades de pointes.

The “atypical” antipsychotic medicines include ziprasidone, risperidone, olanzapine, aripiprazole, and quetiapine. The atypical agents are favored because they produce fewer of the side effects associated with conventional antipsychotic agents, such as acute dystonia, other extrapyramidal symptoms, and sedation. Oral doses should be offered first, and several agents, including risperidone, olanzapine, and aripiprazole, are available in rapidly dissolving tablet form. Three are available as an intramuscular injection: ziprasidone (Geodon), olanzapine (Zyprexa), and aripiprazole (Abilify). Ziprasidone 10 to 20 mg has been shown to be effective; however, its use is limited to 40 mg per 24 hours. Olanzapine 2.5 to 10 mg has also been shown to be effective, but has been associated with postural hypotension, and is not recommended in combination with benzodiazepines due to risk of hypotensive syndrome. Aripiprazole is the newest agent and at doses of 9.75 to 15 mg seems to be the least sedating of the atypicals, but more likely to cause nausea and vomiting.

Immediate psychiatric consultation should begin during the initiation of rapid tranquilization, since patients undergoing rapid tranquilization will generally require hospitalization (Box 109-6).

**Long-Term Treatment**

**Depression**

Effective treatment modalities for depression are grouped into three broad categories: (1) antidepressant medication, (2) psychotherapy, and (3) electroconvulsive therapy (ECT).

**Antidepressant Therapy.** Many effective antidepressants are available for first-episode uncomplicated major depression. After 4 to 6 weeks of therapy, the response rate is usually 60% or greater for all agents. However, 10 to 15% of patients quit medication trials, and many patients in general medical practice are inadequately treated.

Coexistent medical illness, psychotic or bipolar symptoms, substance use, and recurrent or refractory depressive symptoms must be considered in the choice of a medication for treatment of depression. The side effects of tricyclic antidepressants and monoamine oxidase inhibitors, along with strict dietary limitations, have led to the use of selective serotonin-reuptake inhibitors or serotonin-norepinephrine reuptake inhibitors as first-line treatment for depression. Side effects of these agents may include dizziness, sedation, peripheral anticholinergic symptoms, weight gain, sexual dysfunction, neurologic symptoms, insomnia, and anxiety. Frequently another antidepressant, ECT, thyroid hormone, or other psychoactive medication may need to be added for patients with treatment-resistant depression.

**Psychotherapy.** Brief psychotherapy is often initially employed in patients with major depression. Interpersonal psychotherapy, psychodynamic psychotherapy, and group or family therapy are also used with some patients. Psychosocial therapeutic support typically includes community-based support groups that focus on specific individual, occupational, or family/marital issues that arise in depression and are amenable to group and supportive intervention.

Depressed patients benefit most from a combination of somatic therapy (medication and/or ECT) and psychotherapy. All patients with incomplete therapeutic response, recurrent depression, or comorbid conditions (e.g., anxiety/panic, substance abuse) should receive multimodal treatment.

**Electroconvulsive Therapy.** ECT has a high therapeutic success rate and an excellent safety profile but is not a first-line treatment for uncomplicated major depression. In part, this is a result of an undeserved reputation among laypersons that ECT causes “permanent brain damage.” Indications for ECT include severe depression with malnutrition, severe psychosis with agitation, continuing significant suicide risk with ongoing suicidal behaviors, prolonged catatonia, and recurrent depression previously with a positive response to ECT. ECT is more often used as a second-line treatment for patients with moderate to severe depression who have not responded to trials of medication or who cannot tolerate the medication because of side effects or concurrent medical conditions.

**Bipolar Disorders**

Bipolar disorder is treated primarily with mood-stabilizing drugs, including lithium, valproate, carbamazepine, and lamotrigine. Almost all bipolar patients require a mood stabilizer during exacerbation of depression or mania, and most patients benefit from a mood stabilizer for ongoing supportive maintenance treatment as well. Lithium was the first highly effective mood-stabilizing agent for the treatment of bipolar
Valproate is a very effective mood stabilizer with dose-related side effects, most of which clear after an initial period of treatment or with reduced dosage. Valproate can be instituted rapidly in acutely manic bipolar patients. Both lithium and valproate serum levels are routinely monitored during therapy. The therapeutic window is much wider for valproate than for lithium. Carbamazepine also has dose-related side effects but has rare potentially serious side effects.

Mood-stabilizing medications usually take 3 or more weeks to become effective. Some bipolar patients require antipsychotic medications and benzodiazepines in the interim to control symptoms. Some patients with bipolar disorder have significant psychotic symptoms requiring use of a major neuroleptic, such as haloperidol, ziprasidone (Geodon), risperidone (Risperdal), olanzapine (Zyprexa), quetiapine (Seroquel), or aripiprazole (Abilify). After 3 weeks, a second mood-stabilizing medication is often added for patients who have a partial response. Atypical antipsychotics have significant mood-stabilizing properties and studies have shown that they are effective in treating both bipolar mania and bipolar depression (although not all are FDA approved for this indication). For bipolar patients with a depressive episode, adjunctive treatment with antidepressants should be done very cautiously because of associated risks of switching into mania or hypomania. In addition, some recent studies found that antidepressants may not be effective for bipolar depression and may worsen the course of the illness.

Bipolar patients are sensitive to psychosocial stressors, sleep loss, changes in medication dosage, substance abuse, and medical illness. This sensitivity can lead to a marked worsening in a patient’s level of adaptation and functioning. It is helpful to understand these precipitating stressors when developing a therapeutic support plan for patients. Psychosocial therapeutic support, including individual psychotherapy, supportive community groups, family/marital treatment, and occupational support, are important in both the acute phase and the maintenance phase of treatment for bipolar patients.

### KEY CONCEPTS

- Patients with apparent mood disorders should be evaluated for a medical disorder, medication effect, or drug use that can mimic both depression and mania.
- Mood disorders should be suspected in patients with multiple, vague, nonspecific complaints and in patients who are frequent, heavy utilizers of medical care.
- The differentiation of depression and dementia in elders can be difficult but is important, since depression often responds dramatically to treatment.
- Patients with mood disorders should be assessed for their potential for violence or self-harm before discharge.

The references for this chapter can be found online by accessing the accompanying Expert Consult website.
Anxiety is essential to the human condition. Confrontation with anxiety can relieve us from boredom, sharpen our sensitivity, and create the tension which is necessary to preserve human existence.

Rollo May

Acute anxiety and apprehension are common in emergency department (ED) patients. However, many medical entities mimic anxiety disorders, and up to 42% of patients thought to have anxiety disorders are later found to have organic disease. Emergency physicians must thoroughly assess the anxious patient and identify and appropriately treat any underlying medical conditions.

■ PERSPECTIVE

Anxiety is a specific unpleasurable state of tension that forewarns the presence of danger. This uneasiness stems from the anticipation of some imminent danger, the source of which is unknown or unrecognized. Vigilance is a positive consequence of anxiety, helping people to recognize threats quickly, which produces more learning and more intelligence. The capacity to experience anxiety and the capacity to plan are therefore related, with anxiety accompanying intellectual activity as its “shadow.”

Anxiety facilitates performance up to a point with the well-described adrenergic responses to stress that contribute to survival. When responses go beyond this point, further increases in anxiety may lead to deterioration of performance and nonadaptive responses may add to the stress of the patient. The threshold for pain decreases and the person becomes more aware of bodily discomfort. Respiratory, cardiovascular, gastrointestinal, genitourinary, and neuromuscular complaints become prominent. Once the normal reaction to a threat is surpassed and function is impaired, pathologic anxiety (anxiety disorders) is the result.

The emergency physician should not assume anxiety is purely functional because physical discomfort and illness often trigger an anxiety attack. The anxiety state makes significant metabolic demands that may actually cause a marginally compensated organ system to fail. It is the goal of the emergency physician to be able to distinguish between the anxiety and the illness and, if necessary, treat both entities.

■ EPIDEMIOLOGY

Approximately 40 million American over the age of 18 are affected by anxiety disorders each year. This is nearly 20% of the adult population of the United States. Anxiety disorders are among the most prevalent psychiatric disorders, and are the most common psychiatric problem seen by primary care physicians, with 20% of these patients experiencing a type of anxiety disorder. Most people who use primary care services have significant mood and anxiety symptoms, such as panic disorders, generalized anxiety disorders, and depression. Unfortunately, nearly half of these patients exhibit these symptoms but never receive appropriate treatment, in part, because the patients would rather present with a physical complaint to the physician and try to disguise their anxiety, rather than undergo the perceived stigma that goes with psychiatric complaints. Patients with chronic illness and those who make frequent medical visits have higher rates of anxiety and depression. The prevalence of anxiety disorders surpasses that of any other mental health disorder, including substance abuse. In view of the close relationship between alcohol abuse and anxiety disorders, those with anxiety disorders often turn to alcohol and substance abuse as a form of self-medication and the substance abuser frequently develops underlying anxiety in relation to the use of alcohol and drugs.

■ PRINCIPLES OF DISEASE

The precise mechanism for the cause of anxiety has not been established. Noradrenergic, serotonergic, and other neurotransmitter systems all play a role in the body’s response to a stressor. The serotonin system and the noradrenergic systems are common pathways implicated in anxiety. It is believed that low serotonin system activity and elevated noradrenergic system activity are involved. Gamma butyric acid (GABA) is the principal inhibitory neurotransmitter in the central nervous system. Benzodiazepines’ principal mechanism of action is on the GABA_A receptors. The well-established effectiveness of benzodiazepines in the treatment of anxiety has led to the study of the GABA system and its relationship to anxiety. Newer studies are focusing on the role that corticosteroids may play in fear and anxiety. Steroids are thought to induce chemical changes in select neurons that strengthen or weaken certain neural pathways which affect behavior under stress.

Other investigators have found anxiety reactions are associated with aberrant metabolic changes induced by lactate infusion and hypersensitivity of the brainstem to carbon dioxide receptors. Newer research is focusing on the regulatory centers found in the cerebral hemispheres. The hippocampus and the amygdala regulate emotion and memory and are important areas in relation to an individual’s response to fear. Family studies suggest genetic factors are implicated in anxiety, but...
Somatic Symptoms of Anxiety

Many patients entering the unfamiliar environment of the ED are going to experience anxiety and stress, and for some this can be a significant clinical issue. The ED patient encounters a world of both internal and external dangers: assaults on bodily integrity in the form of uncomfortable procedures and forced intimacy with strangers; the atmosphere of illness, pain, and death; and separation from loved ones and familiar surroundings. The patient typically experiences uncertainty about his or her illness, the implications that the illness may have on personal relationships and employment, and the financial burden that may accompany the illness.

The anxious patient can be a diagnostic challenge. The presence of anxiety may represent the patient’s reaction to medical illness or the medical setting or a manifestation of the physical disorder itself, or the anxiety may be an expression of an underlying psychiatric disorder. The distinction between anxiety as a symptom and anxiety as a syndrome may be difficult to make in the ED. There is an overlap between normal situational anxiety and fear, anxiety-like symptoms resulting from a variety of organic disease states and their treatments, and the characteristic presentation of anxiety itself.

The physical symptoms of autonomic arousal (e.g., tachycardia, diaphoresis, light-headedness) may be the only manifestation of anxiety (Box 110-1). Patients may only complain of overall poor health or vague subjective findings when they visit the physician. Classic panic disorder symptoms of chest pain, shortness of breath, and the sense of impending doom will often lead the patient to the ED, especially if it is the primary episode.7 Anxiety associated with organic etiologies is more likely to present with physical symptoms and less likely to be associated with avoidance behavior.9

DIFFERENTIAL CONSIDERATIONS

Medical Illness Presenting as Anxiety

Patients with anxiety disorders may present with apparent physical disease, and many physical diseases may be strongly associated with symptoms of anxiety. Differentiating between these two scenarios is a daunting task for the emergency physician. Several factors help distinguish an organic anxiety syndrome from a primary anxiety disorder10 (Box 110-2). With anxiety, the somatic symptoms can be so prominent that they occupy most of the patient’s attention, making it difficult to differentiate between a primary anxiety disorder or reactive anxiety to a situation or disease. Anxiety disorder classifications, in the Diagnostic and Statistical Manual of Mental Disorders (DSM-IV), include anxiety caused by a general medical condition11 (Box 110-3).

Anxious patients are frequently convinced that their problem is purely physical. The emergency physician must realize that the patient with anxiety is not in control of the symptoms and frequently cannot immediately identify the correct precipitant. Even though the patient may be uncomfortable, uncooperative, impatient, and unreasonable, triage medical personnel must recognize that the patient believes an illness truly exists and is not being consciously manipulative. Because anxiety may be the most obvious symptom of an underlying disease or condition, the patient should be evaluated for exacerbation of known preexisting disease as well as for onset of new illness. The emergency physician must keep in mind that anxiety is associated with increased medical risk in the acute exacerbation of chronic illness.12

The classic scenarios of pulmonary embolism and hyperthyroidism causing anxiety are well documented. Cardiac disease studies indicate poorer outcomes in post-myocardial infarction patients with anxiety than those without documented anxiety. Patients with respiratory diseases, such as asthma or chronic obstructive pulmonary disease, often develop anxiety with their long-standing illnesses. In addition, many of the medications used to treat the above illnesses may induce anxiety.5 The most common organic cause of anxiety is alcohol and drug use, from either intoxication or, more typically, withdrawal states.

Cardiac Diseases

Various psychiatric conditions may present to the ED with complaints of chest pain. Approximately 25% of patients with chest pain that present to the ED have panic disorder. Their panic disorder often goes undiagnosed, resulting in multiple visits and expensive cardiac workups with each visit.13 Some of the symptoms of myocardial infarction and angina pectoris may

---

**BOX 110-1** Somatic Symptoms of Anxiety

- Respiratory
  - Hyperventilation
  - Sense of dyspnea
- Cardiovascular
  - Palpitations
  - Chest discomfort
  - Awareness of missed beats
- Gastrointestinal
  - Dry mouth
  - Difficulty in swallowing
  - Epigastric discomfort
  - Excessive flatulence
  - Frequent or loose stools
- Genitourinary
  - Frequent or urgent micturition
  - Failure of erection
  - Amenorrhea
  - Menstrual discomfort
- Neuromuscular
  - Tremor
  - Aching muscles
  - Prickling sensations
  - Headache
  - Dizziness, tinnitus

---

**BOX 110-2** Predictors of Organic Anxiety Syndrome

1. Onset of anxiety symptoms after age 35 years
2. Lack of personal or family history of an anxiety disorder
3. Lack of childhood history of significant anxiety, phobias, or separation anxiety
4. Lack of avoidance behavior
5. Absence of significant life events generating or exacerbating the anxiety symptoms
6. Poor response to antipanic agents

---

**BOX 110-3** General Diagnostic Considerations

1. Absence of significant life events generating or exacerbating the anxiety symptoms
2. Onset of anxiety symptoms after age 35 years
3. Lack of personal or family history of an anxiety disorder
4. Lack of childhood history of significant anxiety, phobias, or separation anxiety
5. Lack of avoidance behavior
6. Absence of significant life events generating or exacerbating the anxiety symptoms
7. Poor response to antipanic agents

---

The precise nature of the inherited vulnerability is unknown. Psychological and environmental factors, as outlined in psychological, behavioral, and cognitive theories, also play a causative role in the generation of anxiety in biologically predisposed individuals.8

---

**CLINICAL FEATURES**

The classic scenarios of pulmonary embolism and hyperthyroidism causing anxiety are well documented. Cardiac disease studies indicate poorer outcomes in post-myocardial infarction patients with anxiety than those without documented anxiety. Patients with respiratory diseases, such as asthma or chronic obstructive pulmonary disease, often develop anxiety with their long-standing illnesses. In addition, many of the medications used to treat the above illnesses may induce anxiety. The most common organic cause of anxiety is alcohol and drug use, from either intoxication or, more typically, withdrawal states.

**DIFFERENTIAL CONSIDERATIONS**

Medical Illness Presenting as Anxiety

Patients with anxiety disorders may present with apparent physical disease, and many physical diseases may be strongly associated with symptoms of anxiety. Differentiating between these two scenarios is a daunting task for the emergency physician. Several factors help distinguish an organic anxiety syndrome from a primary anxiety disorder (Box 110-2). With anxiety, the somatic symptoms can be so prominent that they occupy most of the patient’s attention, making it difficult to differentiate between a primary anxiety disorder or reactive anxiety to a situation or disease. Anxiety disorder classifications, in the Diagnostic and Statistical Manual of Mental Disorders (DSM-IV), include anxiety caused by a general medical condition (Box 110-3).

Anxious patients are frequently convinced that their problem is purely physical. The emergency physician must realize that the patient with anxiety is not in control of the symptoms and frequently cannot immediately identify the correct precipitant. Even though the patient may be uncomfortable, uncooperative, impatient, and unreasonable, triage medical personnel must recognize that the patient believes an illness truly exists and is not being consciously manipulative. Because anxiety may be the most obvious symptom of an underlying disease or condition, the patient should be evaluated for exacerbation of known preexisting disease as well as for onset of new illness. The emergency physician must keep in mind that anxiety is associated with increased medical risk in the acute exacerbation of chronic illness.

The classic scenarios of pulmonary embolism and hyperthyroidism causing anxiety are well documented. Cardiac disease studies indicate poorer outcomes in post-myocardial infarction patients with anxiety than those without documented anxiety. Patients with respiratory diseases, such as asthma or chronic obstructive pulmonary disease, often develop anxiety with their long-standing illnesses. In addition, many of the medications used to treat the above illnesses may induce anxiety. The most common organic cause of anxiety is alcohol and drug use, from either intoxication or, more typically, withdrawal states.

**BOX 110-3** DEFINITIONS OF ANXIETY DISORDERS

Panic attack is a discrete period in which there is a sudden onset of intense apprehension, fearfulness, or terror, often associated with feelings of impending doom. Agoraphobia is an anxiety about, or avoidance of, places or situations from which escape might be difficult. Panic disorder with agoraphobia is characterized by both recurrent, unexpected panic attacks and agoraphobia. Agoraphobia without a history of panic disorder is characterized by the presence of agoraphobia and panic-like symptoms without a history of unexpected panic attacks. Specific phobia is characterized by clinically significant anxiety provoked by exposure to a specific feared object or situation, often leading to avoidance behavior. Social phobia is characterized by clinically significant anxiety provoked by exposure to certain types of social or performance situations, often leading to avoidance behavior. Blushing is the cardinal characteristic symptom. Obsessive-compulsive disorder is characterized by obsessions that cause marked anxiety or distress and by compulsions that serve to neutralize anxiety. Post-traumatic stress disorder is characterized by experiencing of an extremely traumatic event, accompanied by symptoms of increased arousal and by avoidance of stimuli associated with trauma. Acute stress disorder is characterized by symptoms similar to those of post-traumatic stress disorder that occur immediately in the aftermath of an extremely traumatic event. Generalized anxiety disorder is characterized by at least 6 months of persistent and excessive anxiety and worry. Anxiety disorder caused by a general medical condition is characterized by prominent symptoms of anxiety that are judged to be a direct physiologic consequence of a general medical condition. Substance-induced anxiety disorder is characterized by prominent symptoms of anxiety that are judged to be a direct physiologic consequence of a drug of abuse or medication or toxin exposure. Anxiety disorder not otherwise specified is included for coding (1) disorders with prominent anxiety or phobic avoidance that do not meet criteria for specific anxiety disorders and (2) anxiety symptoms with inadequate or contradictory information.

anxiety disorders in hypothyroid states are more related to the organic mental deficits. Anxiety and progressive mental slowing associated with diminished recent memory and speech deficits with diminished learning ability are the characteristic initial progression of symptoms. The development of severe anxiety disorders in hypothyroid states are more related to the rapidity of change of thyroid hormone levels than the absolute levels encountered. In general, checking the serum thyroid-stimulating hormone and free thyroxine levels will suffice in the ED to make the diagnosis of thyroid emergencies.

Endocrine Diseases

The DSM-IV defines the most common endocrinologic conditions associated with anxiety states as hypoparathyroidism, hyper- and hypothyroidism, hypoglycemia, pheochromocytoma, and hyperadrenocorticism. Anxiety is the predominant symptom in 20% of patients with hypoparathyroidism. Other symptoms include paresthesias, muscle cramps, muscle spasm, and tetany. Most cases are idiopathic or the result of surgical removal of the parathyroid glands during thyroidectomy, and studies indicate a higher incidence of anxiety in the surgically removed subset of patients. The diagnosis of hypoparathyroidism is suggested by a low serum calcium level, a high phosphate level, and confirmed by a parathyroid hormone assay.

Approximately 14% of diabetic patients suffer from anxiety disorders, and elevated anxiety symptoms are seen in up to 40% of diabetics. There is evidence that diabetics who are treated with antianxiety medication not only experience a reduction in anxiety but also a decrease in glycosylated hemoglobin levels and high-density lipoprotein. Many patients with anxiety, somatoform, or characterologic disorders are convinced that they have reactive hypoglycemia. A normal fingerstick blood glucose analysis done during an attack can exclude this diagnosis.

Pheochromocytomas are rare tumors that produce elevated levels of catecholamine in the body. Common symptoms include paroxysmal hypertension, headache, anxiety, sweating, flushing, abdominal and back pain, and vomiting and diarrhea. Pheochromocytoma attacks can present just like panic attacks and can be precipitated by emotional stress. While the sweating associated with pheochromocytoma attacks involves the whole body, the sweating in panic attacks is more likely to be confined to the hands, feet, and forehead. Elevated urinary catecholamine or plasma metanephrine can confirm a pheochromocytoma.

Hyperthyroidism is one of the most frequently encountered endocrine diseases associated with anxiety. As with panic disorders, hyperthyroidism is associated with acute episodic anxiety. Thyrotoxicosis causes anxiety, palpitations, perspiration, hot skin, rapid pulse, active reflexes, diarrhea, weight loss, heat intolerance, proptosis, and lid lag. Psychiatric presentations are often the first sign of hyperthyroidism, occurring as the initial symptom in approximately 2 to 12% of reported cases along with organic mental deficits. Anxiety and progressive mental slowing associated with diminished recent memory and speech deficits with diminished learning ability are the characteristic initial progression of symptoms. The development of severe anxiety disorders in hypothyroid states are more related to the rapidity of change of thyroid hormone levels than the absolute levels encountered. In general, checking the serum thyroid-stimulating hormone and free thyroxine levels will suffice in the ED to make the diagnosis of thyroid emergencies.

Respiratory Diseases

Most conditions causing airway compromise or impairing gas exchange would never be mistaken for a psychiatric disorder. However, certain conditions that cause hypoxemia or hypercarbia may present with significant anxiety, and up to a third
of the patients with chronic obstructive pulmonary disease meet the criteria for anxiety disorder.\textsuperscript{21}

Asthma is characterized by episodic attacks of dyspnea and often anxiety. Anxiety can also precipitate and prolong asthma attacks. Patients who have severe asthma are twice as likely to have an anxiety disorder and almost five times as likely to have a phobia compared with nonasthmatics. Severe asthmatics are almost five times as likely to have a panic disorder and about four times as likely to have a panic attack. Acute dyspnea secondary to asthma is easily differentiated from pure panic in that there is good air movement with normal lung sounds in a patient experiencing a panic attack, but studies consistently show that anxiety disorders increase asthma morbidity and mortality.\textsuperscript{22}

Shortness of breath is a common complaint in the ED. When accompanied by anxiety, panic attacks or anxiety disorders may be high on the differential diagnosis. The clinician must always fully evaluate these patients, as these are often the complaints of a patient presenting with a pulmonary embolism. Acute shortness of breath in any patient should never be dismissed lightly, especially since pulmonary embolus can present with only shortness of breath as the major symptom. These patients can be distinguished by close attention to history and examination, assessing risk factors for thromboembolic disease and use of basic investigations (e.g., pulse oximetry, electrocardiogram, chest radiography, arterial blood gas analysis, and D-dimer) and further tests as indicated.\textsuperscript{23}

Neurologic Disorders

Many neurologic conditions are associated with anxiety symptoms.\textsuperscript{24-26} Temporal lobe seizures, complex partial seizures, tumors, arteriovenous malformation and ischemia or infarction all have been reported to present with panic attacks. Anxiety often accompanies a transient ischemic attack and may be the major symptom on presentation if the transient ischemic attack has resolved by the time the patient reaches the ED. In Huntington’s disease, anxiety has been reported as the most common prodromal symptom. Anxiety occurs in up to 40\% of patients with Parkinson’s disease and up to 37\% of patients with multiple sclerosis. Similarly, anxiety symptoms have been noted to be common in moderate Alzheimer’s disease. The coexistence of anxiety disorders plays an important role in the prognosis and impairment of patients who have had cerebral vascular accidents with neurologic sequelae. Anxiety and depression are associated with left-hemispheric strokes and anxiety alone with right-hemispheric strokes. And finally, anxiety disorders have also been reported in the aftermath of traumatic brain injury.\textsuperscript{27}

Drug Intoxication and Withdrawal States

Amphetamines, cocaine, and sympathomimetic drugs are abused for their stimulant and mind-altering properties. Amphetamine use has exploded over the past decade, and cocaine use is still the drug of choice in many large cities. Patients often present to the ED agitated, anxious, or aggressive when these drugs are taken in large doses and with prolonged use. Caffeine is a common stimulant, and energy drinks and gourmet coffee represent a constantly growing market in the United States. These drinks are packed with caffeine and the herbal equivalent guarana as well as ginkgo biloba. Studies indicate that 240 to 300 mg of caffeine per day should be the upper limit of healthy consumption. Many of these energy drinks contain that amount in a single serving.\textsuperscript{21} Lower doses of caffeine can be pleasantly stimulating, but higher doses cause hyperalertness, hypervigilance, motor tension, tremors, gastrointestinal distress, and anxiety. The acute symptoms of caffeine intoxication and generalized anxiety disorder are almost identical. Stimulants such as Ephedra and ephedrine-based compounds were found in many dietary supplements and listed by the herbal name of Ma Huang. Despite the Food and Drug Administration ban on Ephedra-containing compounds in 2004, access still exists on the Internet.

Many illicit drug users who use marijuana believe that the drug reduces their anxiety. But some experience a depersonalization that provokes severe anxiety, fearfulness, and agoraphobic symptoms. Lysergic acid diethylamide (LSD), phencyclidine (PCP), and ecstasy are hallucinogens that can produce anxiety and paranoia from chronic use or “bad trips.” Flashbacks affect some users of LSD, where the person may experience the symptoms of anxiety and paranoia weeks or months after use.\textsuperscript{26}

Sedative-hypnotic drugs (e.g., benzodiazepines, barbiturates, meperidine, methaqualone, chloral hydrate, and paraldehyde) are taken to relieve anxiety or sleeplessness, but their discontinuation can cause sedative withdrawal and rebound anxiety. The severity of the withdrawal syndrome depends on the drug, dosage, duration of use, and speed of elimination. In general, the intermediate-acting sedative-hypnotics (4–6 hours) cause the worst withdrawal symptoms. These symptoms include hyperalertness, motor tension, muscle aches, agitation, anxiety, insomnia, hyperactive reflexes, postural hypotension, tremulousness, nausea, vomiting, convulsions, delirium, and even death.

Benzodiazepine withdrawal is rarely fatal but can be very unpleasant. In anxious patients, severe rebound anxiety can occur after a few weeks’ use of recommended therapeutic doses. Lorazepam and alprazolam are short-acting agents and their abrupt discontinuation frequently causes panic attacks within 1 to 2 days. With longer-acting agents, withdrawal symptoms typically peak in about one week. Normal people may experience this rebound as stimulating. Although antidepressants are rarely abused, their abrupt withdrawal can also cause an abstinence syndrome of insomnia, vivid nightmares, and extreme anxiety.\textsuperscript{27}

Alcohol withdrawal, in alcohol-dependent individuals or heavy binge drinkers, can appear 6 to 12 hours after the last drink or significant reduction in consumption of alcohol. Patients often have detectable alcohol still in their systems at this time. Anxiety is one of the first and most prominent symptoms and is seen within 24 to 48 hours of the withdrawal state.\textsuperscript{28}

Anxiety in Primary Psychiatric Disorders

Even in patients with known mental illness, a panic disorder is a diagnosis of exclusion because several mental illnesses cause panic attacks as a secondary manifestation. The presence of panic often influences the treatment and outcome of the primary mental illness. Panic attacks can occur as part of a bipolar (manic-depressive) disorder, in either the manic or the depressed phase. In manic and hypomanic disorders the patient’s predominant affect is usually cheerful and euphoric but may also be dysphoric with irritability and extreme anxiety of panic proportions.\textsuperscript{29}

Early in the course of schizophrenia, a patient will often experience panic attacks. Fearfulness, tension, agitation, immobility, disorganized thinking, dilated pupils, extreme insecurity, suspiciousness, and delusions of reference and persecution may characterize schizophrenic panic attacks. The hallucinations often have derogatory accusative content. Social anxiety is a highly prevalent and disabling condition with schizophrenia that is unrelated to clinical psychotic symptoms.\textsuperscript{30}
Patients with somatoform disorders report a variety of somatic symptoms, including panic attacks, and 68% report a history of anxiety. Patients claim to have most of the physical symptoms they are asked about, even when evidence excluding illness is presented to the patient. Fear and anxiety initiate, facilitate, and maintain many of the symptoms encountered in the somatoform patient. Patients with “pure” anxiety disorders tend to be hypochondriacal, while those with somatization are more likely to improve transiently on active medication or placebo but rarely respond so well that they stop seeking unnecessary medical attention. Patients with panic disorders, however, seek at least as much psychiatric attention as those with somatoform disorders.31

Approximately 50% of patients with a primary panic disorder develop major depression and many others are bothered by some degree of depression in mood. Twenty percent of patients with depression have panic attacks, and the remainder have considerable anxiety. Depression with panic attacks responds less well to treatment. Agitated depression with anxiety and psychosis, sometimes called “involutional melancholia,” responds well to electroconvulsive therapy. Depression with anxiety and hostility responds well to antidepressants but benzodiazepines can exacerbate symptoms.32

Post-traumatic stress disorder is an anxiety disorder characterized by the reexperiencing of an extremely traumatic event. The symptoms are closely related to and worsened by reminders of the trauma. The “flashbacks,” in which patients reexperience the original trauma, can have the same symptoms as panic attacks. These patients often avoid crowds or social situations.33

A panic disorder is one of the easier psychiatric diseases to feign because most of the symptoms can be duplicated by intentional hyperventilation. Functional hyperventilation can be distinguished from organic hyperventilation by its irregularity and interruptions by sighs. When in doubt, formal psychiatric evaluation is indicated, particularly before prescribing a potentially dangerous or addictive drug therapy.

A phobia is an irrational fear that results in avoidance and is considered normal in children. The objects of fear tend to be things that seem dangerous to a child (e.g., spiders, snakes, bats, cats, enclosed places, the dark, open spaces). Phobia becomes a disorder when it interferes with day-to-day function in an individual’s life. A social phobia is characterized by clinically significant anxiety provoked by exposure to a specific feared object or situation, often leading to avoidance behavior. Social phobias prevent a patient from doing such activities as public speaking, performing, visiting, using public showers or restrooms, or eating in public places. Agoraphobia is a fear of being alone in public places. Nearly 75% of agoraphobic patients have panic attacks.34 Those with panic attacks are more likely to seek treatment, whereas those with uncomplicated agoraphobia tend to stay at home. Agoraphobia without panic attacks may not differ fundamentally from other simple phobias. Most panic disorder patients have multiple phobias, including agoraphobia. The latter is believed to result from the panic patient’s increasing attempts to avoid places or situations in which the panic attacks would be particularly inconvenient or difficult to control. Agoraphobic patients particularly avoid places from which escape would be difficult (e.g., bridges, crowded theaters). When they do attend theaters, they favor seats on the aisle and near the door. Panic attacks in agoraphobic patients are more likely to include fear of losing control, whereas those not associated with agoraphobia are more likely to include dyspnea and dizziness.35

An obsessive-compulsive disorder (OCD) is characterized by recurrent, obsurive, unwanted thoughts (obsessions), such as fears of contamination, and compulsive behaviors or rituals (compulsions), such as handwashing or checking. OCD is classified as an anxiety disorder because (1) anxiety or tension is often associated with obsessions and resistance to compulsions, (2) anxiety or tension is often immediately relieved by yielding to compulsions, and (3) OCD often occurs in association with other anxiety disorders. In summary, the obsessions and intrusive thoughts increase anxiety and the compulsions and repetitive behaviors decrease anxiety but with significant disruption of one’s life.9

- **MANAGEMENT**

**Initial Evaluation**

The patient should first be placed in a quiet area for evaluation. Some patients calm down when removed from the ED environment. If the emergency physician encounters difficulty in calming the patient, supportive family members may help. Often a known and trusted face helps anxious patients make order out of their inner turmoil. Prior discussion and clarification of the patient’s specific concerns are clarified.1

The extent of the medical workup for significant anxiety will vary depending on the age and health status of the patient, the nature of the anxiety, and the range and severity of associated symptoms. The emergency physician should consider the anxiogenic effects of medications, including beta-adrenergic agonists, theophylline, corticosteroids, thyroid hormones, and sympathomimetics. Potential contributory medical illness (e.g., thyroid dysfunction, hypoglycemic episodes in diabetes, hyperparathyroidism, dysrhythmias, chronic obstructive pulmonary disease, seizure disorders), substance use (e.g., caffeine, amphetamines, cocaine) and withdrawal states (e.g., alcohol, sedative-hypnotics) must also be considered.

If a somatic concern is the major component of the acute anxiety attack, a physical examination with particular attention to the area of complaint is important, even when there is overwhelming evidence of a functional etiology to the patient’s complaints. Anxiety attacks are stressful experiences in themselves and can cause deterioration in marginally compensated organ systems. Careful evaluation reassures the patient and avoids the problem of a premature “medical clearance.” Abnormal vital signs should immediately alert the emergency physician to an organic cause of the anxiety symptoms.9

Because of the physical nature of the symptoms, patients with anxiety and panic attacks often seek treatment in the ED rather than in a psychiatric setting. A calm manner and willingness to listen usually relieves some of the patient’s initial anxiety. An anxiety or panic reaction may be precipitated by the loss of a significant relationship, a job, a living situation, or self-esteem, as well as by physical illness or injury. Once the patient describes a trigger event, the emergency physician should restate it, as if experiencing a similar situation. This gives the patient authoritative approval for expressing embarrassing feelings. A patient who has frequent anxiety reactions is usually suggestible and will respond to reassurance. Conversely, an anxious or unsympathetic physician will only compound the problem.1

Even an apparently calm patient may communicate anxiety through worried looks, nervousness, pressured speech, or
covert assaults on the physician’s competence. In turn, the physician may empathetically respond to the patient’s hidden anxiety by also becoming anxious. This is a strong clue that the patient’s anxiety is real and significant. Without this self-awareness, physicians may focus on a patient’s physical symptoms rather than on the irrational anxiety. The pressure to see patients quickly and to move them out of the ED expeditiously may result in limited interactions with patients, the misdiagnosis of anxiety disorders, and excessive and unnecessary medical workups. A careful medical evaluation is important, but excessive focus on unlikely illness suggests to the patient a reason to worry, avoids recognition of crucial psychological factors, and may increase anxiety and the severity of symptoms.

After organic illness, medications, and obvious psychiatric causes of the acute anxiety state have been ruled out, the physician should determine whether the anxiety is endogenous or exogenous. If the anxiety arises spontaneously without an identifiable stress, is unpredictable, and is accompanied by agoraphobia, an endogenous component is likely to be present. Such patients should be referred to a psychiatrist for evaluation and treatment. If the anxiety appears to be related to an identifiable external event or circumstance, the anxiety is exogenous and patients should be encouraged to discuss their feelings with a mental health worker. Talking about fears allows anxious patients some sense of mastery and control over events. These patients often require ongoing advice, support, and assistance in mobilizing necessary resources from family members, friends, and social agencies to achieve realistic expectations.

Anxiety is common in elders, with prevalence rates conservatively estimated at 10%, with higher rates in patients with chronic illness. Anxiety disorders may be the most common psychiatric ailments experienced by older adults, but that age group is the least studied of all patients. Older patients with anxiety often have somatic complaints. These patients require a careful investigation for underlying medical illness, other psychiatric conditions, and the use of over-the-counter and prescription drugs.

**Pharmacologic Treatment**

Before medication is prescribed, education of the patient about their illness is a key component in the treatment of anxiety disorders. Patients are often worried and confused about their illness. Reassurance that they are not alone, education about what to expect and that therapy is available, and involvement of family are all critical pieces in the treatment of anxiety. Use of intravenous medication is rare but may be necessary when an anxiety state renders a patient so helpless and out of control that there is a significant threat of safety to self or others. Intravenous medication is also appropriate for the anxious patient experiencing a significant medical illness or undergoing a medical procedure. Lorazepam in small increments every 20 minutes can be helpful in alleviating the anxiety associated with substance withdrawal states. Midazolam is frequently used to reduce anxiety and increase amnesia for ED procedures.

Selective serotonin-reuptake inhibitors (SSRIs) have become the first-line treatment for most anxiety disorders because of their broad spectrum of efficacy and good tolerance by most patients. SSRIs have a lower potential for dependence and are safer than the previous classes of antidepressants and anxiolytics. This class of drugs includes fluoxetine, sertraline, fluvoxamine, paroxetine, citalopram, venlafaxine, and sertraline. Improvement is usually seen in 3 to 4 weeks, and the medication may have to be adjusted if no improvements in anxiety are seen. It is important to start the patient on low doses of SSRIs as an initial increase in anxiety may be seen.

In the past few years, emergency physicians and the public have become increasingly concerned about the growing use of benzodiazepines in the United States. Over 1 million Americans are physically dependent on tranquilizers. When tranquilizers are given in place of understanding, support, and intrapersonal therapies, patients are taught to rely on the external support of a pill rather than on inner resources. Benzodiazepines can be prescribed for motivated patients with acute exogenous anxiety for time-limited stress. Patients who are cooperative, employed, educated, married, and aware that their symptoms have a psychological basis are more likely to respond. Benzodiazepines are an attractive alternative to SSRIs when an immediate reduction of symptoms is desired because of the delayed response with SSRIs or a short-term treatment is needed. Benzodiazepines can be given in one or two daily doses to make use of their short half-lives; alternatively, a bedtime dose may minimize daytime sedation and still manifest a daytime anxiolytic effect. Benzodiazepines should not be prescribed for more than a week. Patients who do not improve within a week are unlikely to benefit from the drug. Patients with a history of alcoholism or drug abuse, who are excessively and emotionally dependent, or who become anxious in response to normal stress are at greater risk of drug dependency and are not good candidates for this treatment from an emergency physician. Dependence and abstinence syndromes have been reported to occur with low doses of tranquilizing drugs, especially if they are taken for more than 8 months. Short-acting benzodiazepines (e.g., lorazepam, oxazepam) should be prescribed at low dosages for patients with liver disease, organic brain syndrome, and those taking medications that either depress central nervous system function or inhibit benzodiazepine metabolism and clearance. Withdrawal rebound symptoms are more common with discontinuation of benzodiazepines than with other antianxiety treatments. Short-acting benzodiazepines produce a more severe abstinence syndrome when they are stopped abruptly, and thus many physicians prefer the longer-acting benzo diazepines. For some patients, switching from a short-acting agent (e.g., alprazolam) to a long-acting agent (e.g., clonazepam) can be helpful before initiating a taper.

Buspirone is a nonbenzodiazepine tranquilizer used in the treatment of generalized anxiety disorder. Buspirone does not appear to cause dependency, is less sedating than benzodiazepines, and tolerance does not occur at therapeutic doses. It is the therapeutic lag in efficacy of 2 to 3 weeks that has limited the use of buspirone. It has had variable and sometimes disappointing results in clinical practice, particularly when used in patients with prior exposure to benzodiazepines.

Monoamine oxidase inhibitors (MAOIs) demonstrate high effectiveness in the treatment of social phobia, panic, generalized anxiety disorders, OCD, and comorbid conditions (e.g., atypical depression). MAOIs (phenelzine and tranylcypromine) may be difficult to tolerate and require discipline and strict dietary restrictions and thus are rarely appropriate in the emergency setting.

Tricyclic antidepressants (TCAs) are effective for panic disorders and generalized anxiety disorders but are ineffective for social phobias and, with the exception of clomipramine, are largely ineffective for OCD as well. TCAs have been used effectively for depressive and anxiety symptoms associated with post-traumatic stress disorder. TCAs include imipramine, nortriptyline, desipramine, amitriptyline, and doxepin. The TCAs have been supplanted by the SSRIs as first-line interventions for the treatment of anxiety and depressive disorders.

Patients with endogenous anxiety (panic attacks with or without agoraphobia) should be referred to a psychiatrist to

Nonpharmacologic Therapy

Psychotherapies may be helpful for individuals whose psychological makeup, coping style, interpersonal dynamics, and situational stressors contribute to their pathologic anxiety. The use of supportive, insight-oriented family is helpful when these factors appear prominently in the patient’s presentation.8

Cognitive-behavioral therapy is predicated on the theory that the distress and impairment associated with anxiety and panic are mediated by maladaptive cognitive responses that promote anxiety and avoidance. The core components of cognitive-behavioral therapy for panic disorder include correction of cognitive misperceptions and overreactions to anxiety symptoms, breathing retraining, muscle relaxation, as well as exposure and desensitization to phobic situations. Cognitive-behavioral therapy is very effective, but requires commitment from the patient.8,9

Meditation (e.g., Zen, yoga, transcendental) has been proposed by many authorities, but little clinical data support its efficacy in anxiety disorders. Biofeedback appears promising for the treatment of generalized anxiety disorder. Hypnotic suggestion may be effective because anxious patients tend to be cognitively scattered, unable to focus their attention, and highly suggestible. A hypnotic state can often be induced by certain stimuli.38

These nonpharmacologic techniques take anxious patients out of the future, about which they are frightened, and place them into the present. These techniques should be reinforced by the development of a physically and psychologically healthy lifestyle. A significant social support system not only protects against vulnerability to illness but also is highly anxiolytic. Regular exercise (e.g., dancing, swimming, bicycling, walking, jogging) also promotes tranquility. Encouraging activity that focuses on hand-eye-ear coordination (e.g., painting, playing keyboard, needlework) helps anxious patients regain and maintain control by bringing them into the present.7

DISPOSITION

Many patients with anxiety-related symptoms can be effectively treated in the ED. The emergency physician can proceed with the following general measures:

1. Rule out organic illnesses as cause of anxiety.
2. Evaluate for substance abuse and medications associated with anxiety.
3. Determine whether anxiety is endogenous or exogenous.
4. Clarify what is currently frightening the patient.
5. Evaluate the patient’s capacity for self-awareness.
6. Assess techniques that have worked in the past.
7. Support coping skills.
8. Give the patient as much control over the care plan as feasible.
9. Select patients to start on a short course of benzodiazepines and educate patients about treatment.
10. Apply adjunctive techniques as appropriate for the patient’s personality and the physician’s preference (e.g., hypnotic suggestion, breathing exercises).

Patients with a panic disorder associated with suicidal or homicidal ideation or with severe depression require urgent psychiatric attention and admission to the hospital. Other patients with suspected endogenous or severe exogenous anxiety disorders should be referred for psychiatric evaluation. The Anxiety Disorders Association of America can be contacted (240-485-1001) for a national registry of clinicians and treatment programs specializing in anxiety disorders or can be found online at www.adaa.org.

The references for this chapter can be found online by accessing the accompanying Expert Consult website.
Occasionally patients present to the emergency department (ED) with a myriad of physical symptoms but no apparent physical disease. This presents a vexing conundrum for the physicians who are wary of missing subtle presentations of physical disease. Even when a somatoform disorder is strongly suspected, emergency physicians are reluctant to attribute physical complaints to functional etiologies.1

In one study, 20% of 1500 consecutive patient visits to primary care physicians involved somatization.2 The prevalence of somatization has risen over the past 30 to 40 years, possibly because of a general decline of patients’ tolerance for mild and self-limited ailments.3,4

It is not unusual for physicians to feel that patients with somatoform disorders have nonlegitimate disturbances, because their presentation and diagnosis are more generally felt to be the province of psychiatry and not emergency medicine. Nevertheless, proper diagnosis and treatment of patients’ somatoform disorders is essential, as misidentification and mismanagement unnecessarily prolongs patients’ distress and adds to the overall burden on the health care delivery system.

Somatization refers to a tendency to experience and communicate psychological distress as physical symptoms in the absence of identifiable pathology.5,6 Patients with somatization disorders seek medical attention because they are convinced that their symptoms reflect real physical disease.7–11 In direct contrast to malingering and factitious disorder, the symptoms are neither feigned nor under the voluntary control of the patient.12,13 Somatization is most often associated with concurrent depressive and anxiety disorders.14

Somatization Disorder
Historically referred to as hysteria and neurasthenia, somatization disorder was given the eponym Briquet’s syndrome by Guze in 1975 to avoid the pejorative implications associated with the traditional terms.27,28 The malady is chronic or
Criteria for the Diagnosis of Somatization Disorder

1. There must be a history of medically unexplained physical symptoms beginning before the age of 30 years.
2. A history of all of the following:
   a. Pain related to at least four different sites (e.g., head, abdomen, back, joints, chest) or functions (e.g., during menstruation, during urination)
   b. At least two gastrointestinal symptoms other than pain
   c. At least one sexual or reproductive symptom other than pain (e.g., sexual indifference, irregular menses)
   d. At least one symptom or deficit suggesting a neurologic condition not limited to pain (e.g., paralysis, lump in the throat, blindness)
3. Either the above symptoms must not be explainable by any known medical condition or, when there is a related general medical condition, the complaints or impairment must be out of proportion to what might be reasonably expected.
4. The symptoms must not be intentionally produced or feigned.

The diagnosis of somatization disorder requires several criteria (Box 111-1). This diagnosis is rarely made in the ED, even though it may be suspected, because the proper investigation of this disorder involves time-consuming interviews and may require four to six visits before the establishment of a definitive diagnosis. Many patients do not meet the criteria for a strict diagnosis of somatization disorder yet still have considerable functional impairment, psychological distress, and excess health care utilization. A short list of symptoms provides a rapid screen for this disorder. The seven symptoms that best discriminate between patients with and without somatization disorder are (1) dysmenorrhea, (2) the sensation of a “lump” in the throat, (3) vomiting, (4) shortness of breath, (5) burning in the sex organs, (6) painful extremities, and (7) amnesia lasting hours to days. Among patients displaying at least two of these symptoms, the diagnosis of somatization disorder is correctly predicted with a sensitivity of 93% and a specificity of 59%. When four or more of these seven symptoms are present, the specificity rises to 100%. Although this screening may identify patients at high risk for somatization disorder, such patients should still be evaluated thoroughly to confirm the diagnosis and exclude organic disease.

True somatization disorder is relatively uncommon, having a prevalence of 0.06 to 2% among the general population and up to 9% among hospitalized patients. It tends to run in families and is rarely diagnosed in men, although in some cultures the prevalence in men and women may be the same. The typical patient is a woman in her 40s who has a 25-30-year history of multiple vague complaints, usually headache, dizziness, nausea and vomiting, syncope, abdominal pain, bowel trouble, fatigue, palpitations, dyspareunia, and dysmenorrhea. Symptoms usually date back to the patient’s teens and 20s, with menstrual complaints being common in these age groups. Only 33% of patients recover during 10- to 20-year follow-up, and new symptoms requiring medical attention tend to surface at least every year. Despite a “lifetime of suffering,” the life span of these patients is normal.

Somatization disorder is associated with lower socioeconomic groups, alcoholism and other addictions, and poor education; fewer than 25% graduate from high school. Many have occupational, interpersonal, and marital problems.

The health care utilization and functional impairment of these patients are astounding. Expenditures for physician services are 14 times greater and overall health care expenditures nine times greater than for unaffected patients. The typical patient spends 7 days in the hospital each year and 7 days sick in bed each month (compared with less than a half-day for a control population). More than 82% stop work because of their health. When the diagnosis is recognized, however, medical resource use among these patients tends to normalize.

Patients with somatization disorder describe their symptoms in dramatic exaggerated fashion using colorful language, with great detail about how their lives have been disrupted. They usually admit to being sickly throughout life. Although extensive, their narrative suggests no clear diagnostic constellation. Patients offer detailed accounts of multiple prior medical encounters, termed “doctor shopping,” and often display multiple abdominal scars because they undergo two to three times the number of surgeries of other patients. Their medical records have numerous and exotic test results, and they faithfully consume an impressive array of medications acquired from multiple primary physicians and specialists. They report allergies to a comprehensive list of antibiotics and analgesics. These patients are often emotional and vain, exhibit limited interpersonal skills, and have few close personal relationships. They are typically dependent and highly manipulative.

Of these patients, 68% fulfill the criteria for histrionic personality disorder. Somatization disorder may be closely related to some anxiety and affective disorders; more than 80% of patients with somatization disorder report a lifetime history of major depression and 68% a history of anxiety. These individuals may threaten or attempt suicide. Completed suicide is usually associated with psychoactive substance abuse. Women with this disorder tend to marry men with antisocial personalities. The husband is often overly solicitous, demanding that his wife receive many clinical studies and quick, decisive action. Predictably, he usually shows some degree of dissatisfaction with physicians in general.

Patients who do not meet the full criteria of somatization disorder but have suggestive symptoms for 6 months or longer are classified as having undifferentiated somatoform disorder, which is treated similarly to somatization disorder.

Conversion Disorder

Also known as hysterical neurosis, conversion type, the rare conversion disorder is characterized by the sudden dramatic onset of a single symptom, typically simulating some nonpainful neurologic disorder for which there is no pathophysiologic or anatomic explanation. In contrast to somatization disorder, conversion disorder typically revolves around a single physiologically impossible condition. The symptoms, generally conforming to the patient’s own idiosyncratic ideas about illness, are not under the patient’s voluntary control. Some symptoms provide gratification for unconscious dependency needs; other symptoms provide escape from painful external stimuli (e.g., hysterical paralysis in battle). Although the symptoms may have a symbolic relationship to the precipitating factors, this is often not the case. The most common conversion symptoms are voluntary motor or
sensory functions and are therefore called pseudoneurologic (Box 111-2).\textsuperscript{12} The most common ED presentations are pseudoseizures, syncope or coma, and paralysis or other movement disorders.\textsuperscript{47}

Most patients are women, except for those in military service and industrial accidents.\textsuperscript{12,41} Conversion disorder typically appears in adolescence and early adulthood and is more common among lower socioeconomic groups. Symptoms tend to be of sudden onset, waxing and waning in response to environmental stresses.\textsuperscript{7,9,10,31,40} The history may show similar symptoms in the past, as well as anxiety, depression, phobias, and sexual disturbances.\textsuperscript{31} Up to 29% of patients have a history of past psychiatric illness.\textsuperscript{47} Patients describe their symptoms with a lack of appropriate concern about their profound bodily dysfunction, termed \textit{la belle indifférence}, although, this presentation is not necessary for diagnosis of conversion disorder, since it may be absent in over 50% of patients and is also seen in organic disease.\textsuperscript{48}

**Pain Disorder**

Also termed somatoform pain disorder,\textsuperscript{7} this condition is similar to conversion disorder in that stressful events are translated into somatic symptoms. The primary and often exclusive symptom is distressful pain that (1) is not intentionally feigned, (2) is persistent in nature, (3) limits daily function, (4) involves one or more organ systems, and (5) cannot be pathophysiologically explained.\textsuperscript{12,13,31} The pain most frequently occurs in the face, low back, neck, or pelvic area and causes significant functional impairment, ultimately becoming a major focus in the patient’s life.\textsuperscript{9,10,12,20} One half of all patients have some precipitating traumatic event at the outset (e.g., motor vehicle accident, industrial injury).\textsuperscript{7} Chronic pain behavior patterns are typically fixed within 3 months after the onset of symptoms, and patients who do not resume normal activities within 2 weeks deserve reevaluation and a careful psychosocial review.\textsuperscript{7} Associated features include frequent visits to physicians despite medical reassurance, excessive use of analgesics, requests for surgery, and eventually the role of permanent invalid after the pain has forced the patient to discontinue gainful employment.\textsuperscript{47}

Onset occurs most often in the 30- to 50-year-old age group but can occur at any age. Symptoms such as headaches or musculoskeletal pain are more likely in women.\textsuperscript{7,9,12} The pain often approximates real pain from physical disease that the patient has experienced in the past (e.g., the patient with a history of pancreatitis may develop recurrent epigastric pain when stressed). Frequent surgical intervention may produce multiple and genuine iatrogenic pain symptoms.\textsuperscript{20}

**Hypochondriasis**

The term \textit{hypochondriasis} comes from \textit{regio hypochondriaca}, a Latin term referring to the upper lateral regions of the abdomen inferior to the costal cartilages, especially the area of the spleen, which early physicians presumed to be the seat of this disorder. Hypochondriasis has four characteristics: (1) physical symptoms disproportionate to demonstrable organic disease; (2) a fear of disease and a conviction that one is sick, leading to “illness-claiming behavior” (a compulsive insistence on being considered a physical cripple); (3) a preoccupation with one’s own body; and (4) persistent and unsatisfying pursuit of medical care (doctor shopping) with a history of numerous procedures and surgeries and eventual return of symptoms.\textsuperscript{31}

These unfortunate patients manifest both a heightened awareness and an unrealistic interpretation of normal physical signs or sensations, such as bowel habits, heartbeat, sweating, or peristalsis. These sensations are perceived as abnormal, noxious, and alarming, a phenomenon known as amplification.\textsuperscript{35} These aberrant perceptions result in a chronic morbid preoccupation with bodily functions and a lingering fear of having a disease despite medical reassurance.\textsuperscript{7,12,13,31} A distinguishing feature of hypochondriasis is that the patient’s symptoms do exist and often are confirmed by physical examination, but the patient exaggerates and misinterprets them.

Hypochondriasis is relatively common. Its prevalence in general medical practice ranges from 4 to 9%.\textsuperscript{12} It has a peak incidence among men in their 30s and women in their 40s, affecting men and women equally.\textsuperscript{9,10,21} Hypochondriacs have an increased sense of responsibility for, and place high value on, their personal health and physical appearance. They have an acute sense of body vulnerability and a heightened aversion to death and aging.\textsuperscript{42} There is a strong correlation of hypochondriasis with major depression.\textsuperscript{31} A milder form of this disorder may be an exaggerated interest in bodily function and health (“health nuts”).\textsuperscript{49}

The hypochondriac complains at length and in detail, using medical jargon. The complaints focus on the head, neck, and trunk, often in the form of pain. Hypochondriacs often believe they have lost control of their lives and have been described as “experts at defeating doctors in order to feel more powerful.”\textsuperscript{31} Consequently, physicians perceive hypochondriacal patients as more angry and hostile than other patients.\textsuperscript{50} The diagnosis may be suggested when the physician feels “frustration, helplessness, or anger associated with a wish to be rid of the patient.”\textsuperscript{22,31}

Reactive hypochondriasis, or transient hypochondriasis, is an acute response to a psychosocial stress or life crisis, such as an acute myocardial infarction, terminal illness, or recent loss of a family member. In contrast to true hypochondriasis, this form is reversible and does respond to reassurance.\textsuperscript{31,49}

**DIAGNOSTIC STRATEGIES**

Physicians are generally unwilling to consider somatoform disorders in their initial differential diagnosis. The often dramatic presentation of symptoms creates a sense of urgency to take action, a fear of undiscovered medical illness, and a subsequent exhaustive evaluation of every complaint. Repetitive or extensive diagnostic testing rarely excludes organic disease.
with absolute certainty, however, and may yield false-positive results, prompting further testing. Somatizing patients are more likely to have morbidity from repeated or invasive evaluations than from undiagnosed organic disease.1

Yielding to the temptation to institute further diagnostic procedures or interventions typically leads to a temporary improvement, closely followed by renewal of symptoms and mutual physician-patient disappointment. This gives rise to inevitable dissatisfaction of the patient with the physician and vice versa, leading to an unsatisfactory parting of ways and a perpetuation of the doctor-shopping cycle.31

Managed care and capitated reimbursement have created an additional quandary by restricting the supply of care in a time of rising demand for care from patients whose symptoms are relatively minor.3,36 The most effective diagnostic tool with somatizers is the interview. Evaluation starts with a thorough but focused history and, if available, a review of the patient’s medical record. This is followed by a careful problem-oriented physical examination, with meticulous inspection of the area of complaint, and simple or routine diagnostic testing, when appropriate, until attaining a reasonable level of diagnostic certainty.16 Further investigations or hospital admissions should be initiated solely on the basis of new objective signs of disease and only after confirming that the tests have not been performed. One rule of thumb in ordering laboratory tests is to do exactly what would be done if the patient were not a somatizer.16,22 However, the clinician must resist the impassioned entreaties of the patient when it is clear that further complex or hazardous studies are unlikely to be productive.9,10,16,52

Multiple medical and surgical consultations generally prove counterproductive. Hypochondriacs perceive this as a test of their claim to illness and respond simply by propagating and demonstrating symptoms with redoubled zeal.31

Differential Considerations

Distinguishing between the various somatoform disorders is less important than the diagnosis of treatable organic disease or the detection of anxiety and depression, which are both more common and more likely to respond to treatment. Coexistent depression or anxiety disorder should always be considered.4,53 Patients who have a relatively recent onset of somatization are more likely than patients with long-standing complaints to be exhibiting subtle signs of acute psychosis, organic brain syndrome, grief reaction, depression, or anxiety.

Depression

Approximately 50 to 70% of depressed patients consult their physician for various somatic complaints.34 Depressed patients may not be aware of a depressed mood or may feel their depression is secondary to the somatic symptoms.53 As a result, depression is the psychiatric disorder most often mistaken for somatoform disorder.13

Although somatoform disorders often coexist with depression, the two conditions must be distinguished. Depression is worse in the morning, better at night, and often associated with a positive family history. The patient is reluctant to describe the symptoms and has vegetative signs of depression (e.g., sleep disturbances, decreased appetite with weight loss).52,53 Pain is a common symptom, particularly headache and pain involving the back, chest, or pelvic area.53,54 Somatoform disorders, on the other hand, are worse at the end of the day, and patients have a marked propensity to discuss their symptoms, usually do not have a family history, and show no vegetative signs.31

In general, elderly patients do not have more physical symptoms than younger patients. Multiple somatic complaints should not be dismissed as a normal consequence of aging but rather considered a symptom of another underlying problem, usually depression or medical disease. Older patients may communicate somatic complaints as a way of expressing anger and provoking guilt among family members.21

Anxiety

Patients with acute anxiety often hyperventilate and frequently exhibit physical signs of increased sympathetic activity. They may be hypervigilant and irritable and may show signs of muscular tension.31 They may offer a history of excessive worrying about their health, feeling “on edge” or irritable, having difficulty relaxing, or sleeping poorly or having trouble falling asleep and report symptoms of headache, tingling, dizzy spells, and diarrhea.55 Patients with somatoform disorders have a high prevalence of anxiety disorders, especially generalized anxiety disorder.56

Physical Illness

When patients with somatization disorder develop true organic disease, they present similar to other patients, with specific complaints, clear chronology, and objective findings that should be appropriately investigated.32 Unfortunately, subjective reports of distress are often not dependable in these patients, and the physician must rely on more objective evidence, including the physical examination and routine laboratory tests.22 Multiple physical symptoms starting late in life are frequently the result of physical disease.7,12 In addition, patients who have a short duration of symptoms are more likely to have organic disease.

Although any organic disease may be mistaken for a somatoform disorder, the occasionally bizarre and atypical manifestations and presentations of the disorders listed in Box 111-3 merit special consideration.13

Factitious Disease and Malingering

Patients with somatoform disorders are not deliberately feigning illness; they are exhibiting the result of an unconscious behavior modification. For a subset of patients, they have unintentionally secured secondary gain from the sick role in the form of sympathy, encouragement, attention, support, and relief from responsibilities and challenges without significant loss of self-esteem.89 In contrast, factitious disorder and malingering are both characterized by the intentional and conscious

**Box 111-3**

**Organic Diseases That May Be Mistaken for Somatoform Disorders**

- Endocrine disorders: hyperparathyroidism, thyroid disorders, Addison’s disease, insulinoma, panhypopituitarism
- Poisonings: botulism, carbon monoxide, heavy metals
- Porphyria
- Multiple sclerosis
- Systemic lupus erythematosus
- Wilson’s disease
- Myasthenia gravis
- Guillain-Barré syndrome
- Uremia
simulation or production of disease (see Chapter 112). Because such deception is difficult to uncover in the ED, these patients are often mistaken for having a somatoform disorder.

## MANAGEMENT

The symptoms of conversion disorder may provide a protective coping value for the patient, and the physician should be cautious about removing them without first providing adequate psychological support and treatment. Otherwise, new symptoms may arise to replace previous ones. The external precipitating stress or cause of anxiety should be removed if possible. These patients require psychiatric evaluation and management, and psychiatric consultation in the ED can be beneficial.47

Recurrence is common, but the prognosis associated with an individual episode of conversion disorder is good and the likelihood of recovery from symptoms exceeds that of other somatoform disorders.12,21,41 Factors associated with a good prognosis include (1) good premorbid health, (2) absence of organic illness or concomitant major psychiatric syndromes, (3) acute and recent onset, (4) definite precipitation by a stressful event, and (5) presenting symptoms of paralysis, aphonia, or blindness.32

### Reassurance

Young patients with no underlying medical or psychiatric illnesses who present with somatization in response to a clear psychosocial stress can often be reassured successfully with an appropriate explanation of their symptoms. Patients with chronic somatization, however, perceive this as an official denial of their sick role and are almost invariably unwilling to accept reassurance. Because they desire the acknowledgment and recognition that come with the designation of illness, which they feel is rightfully theirs, they are disappointed when no pathologic condition is discovered. Conversely, they are elated when given a diagnosis, but they resist recovery because subconsciously the “specter of cure” poses a threat to their sick role.49 Accordingly, attempts to cure the condition are countered with side effects, allergic reactions, and new symptoms. Such patients require another management strategy.

### Legitimizing of Symptoms

Most patients with chronic somatization interpret a psychological explanation for their symptoms as an accusation of lying or feeblemindedness. It is important to convince them that the physician believes in their symptoms and will not try to “talk them out of it.” The priority is to listen and truly understand what the patient is feeling and trying to convey. Suffering is always a subjective phenomenon and, in that sense, is genuine in these patients.29 The physician should convey empathy for the patient’s physical discomfort. If the physician acknowledges the legitimacy of the claim to illness and assures the somatizer of ongoing care, limits may be set on the patient’s illness behavior.9,10,16,31

Patients should be allowed to tell their story without interruption. They should be told that they have an illness that causes them to experience many symptoms but that these symptoms will not lead to medical deterioration.1,5,16 The physician should offer only guarded projections regarding chances for complete “cure” of the condition. Ironically, this may be better received by these patients than overly optimistic assurances because the former serves to safeguard their sick role and shifts the physician away from an adversarial position.16,32

### Diagnosis

Diagnostic labels are of critical importance for somatizers, but the precise meaning of the term should be clarified for the patient to avoid misinterpretation. Explanations for symptoms that incorporate somatic responses and descriptions such as hyperventilation, tension headache, muscle tension, muscle strain, chest wall muscle spasm, or stress may be better accepted than purely psychiatric diagnoses. This reassures the patient that the physician shares the belief that the symptoms result from socially acceptable ailments while allowing more in-depth explanations that incorporate the relationship of bodily function to psychological stress. This, in turn, serves as a preparation for future psychiatric consultation or psychotropic medication.8–10,52

At times, the best approach may be to share the diagnostic uncertainty with the patient, using such terms as “atypical pain” or “multiple complaints following injury.” On a broader scale, managed care organizations must be encouraged to educate their enrollees about the process of somatization, the negative side effects of medications and other interventions, and the range of bodily symptoms in healthy people.3

### Medications

Patients with somatoform disorder have a high affinity for medications and are reluctant to discontinue drugs, even those with no benefit.31 Physicians should avoid drugs that produce an abstinence syndrome or dependence and those that cannot be safely continued indefinitely.32 Pain medications, if given, should be prescribed for regular intervals, not “as needed.”31 Patients with somatoform pain disorder may benefit significantly from treatment with antidepressants, including tricyclic antidepressants.38 Patients with somatization disorder with major depression may also improve with pharmacologic management of the depression.45

Therapy should be kept simple and limited to exercise, diet, physical therapy, and vitamins when possible.52 Hospitalization and narcotics should be avoided. Benign remedies, such as lotions, nutritional supplements, elastic bandages, and heating pads, may be helpful.16,22 Drug regimens should be simplified and only the most distressing symptoms addressed. Before starting any type of symptomatic drug treatment, specific target symptoms should be identified. The goal is to restore function and to make the target symptoms tolerable, not to remove them completely. If ED patients request an increase in dosage or a stronger medication, they should be told to review their medications with their regular physician before any changes are made. Insistent patients should be informed that long-term opioid use is associated with significant adverse effects, especially constipation, sedation, impaired cognition, and progressive development of tolerance and addiction.25

### Mental Health Consultation

Patients with somatoform disorders have difficulty confronting their own emotions, view psychiatric evaluation as threatening to their sick role, and take offense at any suggestion that their fears or beliefs may be unwarranted.7,41 They usually resist psychiatric consultation and interpret it as an attempt to be “dumped on the psychiatrist.”31 Nevertheless, psychiatric consultation may be appropriate (1) to confirm the diagnosis or discuss medications, (2) when the patient has coexistent manifestations of chronic depression or psychosis, (3) when symptoms suddenly change or become bizarre, (4) when the patient expresses suicidal ideation or severely disruptive behavior, (5)
when current management is not working, or (6) when the patient requests psychotherapy. Favorable prognostic indicators include youth, acute onset, concurrent anxiety or depression, and limited medical comorbidity. Many patients accept psychological treatment under the rubric of “stress management” as long as it targets physical symptoms and somatic distress. Group therapy techniques presented as education rather than psychotherapy have had some limited success. Patients should be reassured that their relationship with the primary physician will continue to avoid the false interpretation that the referral is an abandonment.

**Physician Attitudes**

The key to diagnosing and treating patients with somatoform disorder is effective and appropriate communication skills on the part of the physician. Somatizing patients can present a challenge because it is tempting to point out to them that there is nothing “wrong” with them and that their symptoms need no treatment. Physicians caring for these patients predictably react with feelings of uncertainty, helplessness, anger, or guilt when they cannot find any physiologic pathology to explain the patient’s distress. Patients with somatoform disorders can become as frustrated with their physician as the physician is with them. It is common for patients with a somatoform disorder to be quickly labeled as a “difficult patient” by the physician and staff. Unfortunately, the frustration of working with these patients quickly overwhelms the physician’s natural tendency towards compassion and can lead to a swift breakdown in communication. Despite the large number of distressing symptoms reported, physicians rarely demonstrate empathy with these patients.

**Treatment Goals**

Somatizing patients, despite lack of objective physiologic pathology, are, in fact, patients who are in need of tangible and effective help. For some, attaining invalid status enables them to be cared for and nurtured. It offers them a sense of self-importance and respect not otherwise available to them, as well as an honorable release from noxious personal and vocational responsibilities and duties. To attempt a cure poses a threat to this role, and unduly positive projections by physicians are therefore understandably met with disappointment, disbelief, and even thinly veiled reproaches regarding their professional competence. Thus, the goal of therapy must control disability and appropriate referrals, rather than cure. The course of management most likely to prove successful begins with performing a sympathetic and thorough problem-oriented history and physical examination, then offering the patient the paradoxical reassurance that he or she will probably always be ill. When pain is the dominant feature, the patient should not be promised complete relief; rather, a major task of the patient should be to “learn to live with some pain.”

Treatment goals should focus on modification of illness behavior and improvement of functional status. Achievable endpoints include (1) decreased frequency and urgency of medical use, in particular a reduction in ED and unscheduled office visits; (2) avoidance of expensive and hazardous procedures; (3) improved work or school performance; (4) more social activities; and (5) better personal relationships. These principles apply equally to pediatric patients with somatoform disorders. Unnecessary tests and procedures, in addition to placing the patient at risk, may encourage somatization. Physician acknowledgment of the patient’s suffering and family concerns, a “rehabilitative” approach emphasizing return to normal activities prior to definitive symptom relief, rewarding healthy behavior and discouraging the sick role, assumption by the patient of responsibility for coping with the symptoms, and treatment of coexistent anxiety or depression are the cornerstones of therapy.

Patients with somatoform disorder have been described as the “least insightful, the least introspective and the least cognitively oriented patients one is likely to encounter.” Understanding the link between emotional and somatic distress need not be a treatment goal for these patients, and insight-oriented psychotherapy is neither productive nor cost effective. On the other hand, both the physician and the patient must accept fundamental alterations in the traditional paternalistic physician-patient relationship. Increasing responsibility for health and disease management must be incrementally turned over to the somatizing patient.

**DISPOSITION**

Appropriate psychiatric referrals should be provided for the patient. Outpatient tests or hospitalization should be avoided unless clear objective signs indicate a need for diagnostic investigation or therapeutic intervention. As a rule, management is best carried out by a single primary care physician who becomes the gatekeeper for all medical consultation and care. The patient should be told that no alarming findings have come to light, that further testing and additional medications are not indicated at this time, and that ongoing care and periodic reassessment is indicated and will be arranged. Patients with chronic somatization should initially be seen every 2 to 4 weeks, preferably by their primary care physician, even if their symptoms are stable. The visits should be on a time-contingent, not a need-contingent, basis. For the patient, this severs the association between medical contact and the necessity for worsening or additional symptoms and complaints. It also decreases the patient’s fear of abandonment by the physician and permits repeated evaluation for early detection of objective signs of organic disease.

PERSPECTIVE

Patients may present to the emergency department with symptoms that are intentionally produced or simulated. The inducements that generate this behavior define two distinct varieties: factitious disorders and malingering.

Factitious disorders are characterized by symptoms or signs that are intentionally produced or feigned by the patient in the absence of apparent external incentives. Factitious disorders have been present throughout history. In the second century, Galen described Roman patients inducing and feigning vomiting and rectal bleeding. Hector Gavin sought to categorize this behavior in 1834. These patients constitute approximately 1% of general psychiatric referrals, but this percentage is somewhat lower than that seen in emergency medicine because these patients rarely accept psychiatric treatment. Of patients referred to infectious disease specialists for fever of unknown origin, 9.3% of the disorders are factitious. Between 5% and 20% of patients followed in epilepsy clinics have psychogenic seizures, and in some primary care settings the number reaches 44%. Among patients submitting kidney stones for analysis, up to 3.5% have been found to be fraudulent.

Munchausen syndrome, the most dramatic and exasperating of the factitious disorders, was originally described in 1951. This fortunately rare syndrome takes its name from Baron Karl F. von Munchausen (1720–1797), a revered German military officer and noted raconteur who had his embellished life stories stolen and parodied in a 1785 pamphlet. The diagnosis is appropriate for only 10 to 20% of patients with factitious disorders. Other names applied include the “hospital hobo syndrome” (patients wander from hospital to hospital seeking admission), peregrinating (wandering) problem patients, hospital addict, polysurgical addiction, laparotomaphilia migrans, Kopenickades syndrome, Ahasuerus syndrome, and hospital vagrant.

Munchausen syndrome by proxy (MSBP) is an especially pernicious variant that involves the simulation or production of factitious disease in children by a parent or caregiver, and was first described in 1977. There are approximately 1200 estimated new cases of MSBP per year in the United States. The condition excludes straightforward physical abuse or neglect and simple failure to thrive; mere lying to cover up physical abuse is not MSBP. The key discriminator is motive: the mother is making the child ill so that she can vicariously assume the sick role with all its benefits. The mortality rate from MSBP is 9 to 31%. Children who die are generally younger than 3 years, and the most frequent causes of death are suffocation and poisoning. Permanent disfigurement or permanent impairment of function resulting directly from induced disease or indirectly from invasive procedures, multiple medications, or major surgery occurs in at least 8% of these children. Other names applied include Polle’s syndrome (Polle was a child of Baron Munchausen who died mysteriously), factitious disorder by proxy, pediatric condition falsification, and Meadow’s syndrome.

Malingering is the simulation of disease by the intentional production of false or grossly exaggerated physical or psychological symptoms, motivated by external incentives such as avoiding military conscription or duty, avoiding work, obtaining financial compensation, evading criminal prosecution, obtaining drugs, gaining hospital admission (for the purpose of obtaining free room and board), or securing better living conditions. The most common goal among such “patients” presenting to the emergency department is obtaining drugs, whereas in the office or clinic the gain is more commonly insurance payments or industrial injury settlements. Because of underreporting, the true incidence of malingering is difficult to gauge, but estimates include a 1% incidence among mental health patients in civilian clinical practice, 5% in the military, and as high as 10 to 20% among patients presenting in a litigious context. A survey by the American Board of Clinical Neuropsychology members revealed the most likely conditions to be feigned were mild head injury, fibromyalgia, chronic fatigue syndrome, and chronic pain.

CLINICAL FEATURES

Factitious Disorders

With a factitious disorder, the production of symptoms and signs is compulsive in that the patient is unable to refrain from the behavior even when its risks are known. The behavior is voluntary only in the sense that it is deliberate and purposeful (intentional) but not in the sense that the acts can be fully controlled. The underlying motivation for producing these deceptions, securing the sick role, is primarily unconscious. Individuals who readily admit that they have produced their own injuries (e.g., self-mutilation) are not included in the category of factitious disorders. Presentations may be acute, in response to an identifiable recent psychosocial stress (termination of romantic relationship, threats to self-esteem), or a chronic life pattern, reflective of the way the person deals with...
life in general. The symptoms involved may be either psychological or physical.

**Psychological Symptoms**

This disorder is the intentional production or feigning of psychological (often psychotic) symptoms suggestive of a mental disorder. Stimulants may be used to induce restlessness or insomnia, hallucinogens to create altered levels of consciousness, and hypnotics to produce lethargy. This psychological factitious condition is less common than factitious disorders with physical symptoms and is almost always superimposed on a severe personality disorder.2,17

**Physical Symptoms**

The intentional production of physical symptoms may take the form of fabricating symptoms without signs (e.g., feigning abdominal pain), simulation of signs suggesting illness (e.g., fraudulent pyuria, induced anemia), self-inflicted pathology (e.g., producing abscesses by injecting contaminated material under the skin), or genuine complications from the intentional misuse of medications (e.g., diuretics, hypoglycemic agents).24 These patients are predominantly unmarried women younger than 40 years. They typically accept their illness with few complaints and are generally well-educated, responsible workers or students with moral attitudes and otherwise conscientious behavior.21,27,28 Many are in health care occupations, including nurses, aides, and physicians.

These patients are willing to undergo incredible hardship, limb amputation, organ loss, and even death to perpetuate the masquerade.21 Although multiple hospitalizations often lead to iatrogenic physical conditions, such as postoperative pain syndromes and drug addictions, patients continue to crave hospitalization for its own sake. They typically have a fragile and fragmented self-image and are susceptible to psychotic, and even suicidal, episodes.27 Interactions with the health care system and relationships with caregivers provide the needed structure that stabilizes the patients’ sense of self. The hospital may be perceived as a refuge, sanctuary, or womb-like environment.2,21,24,28 Some patients are apparently driven by the conviction that they have a real, but as yet undiscovered, illness. Consequently, artificial symptoms are contrived to convince the physician to continue a search for the elusive disease process.21 Factitious illness behavior has even emerged on the Internet. “Virtual support groups” offering person-to-person communications through chat rooms and bulletin boards have been perpetrated by individuals, under the pretense of illness or personal crisis, for the purpose of extracting attention or sympathy, acting out anger, or exercising control over others.26

There has been increasing recognition of factitious illness produced by children (distinct from the MSBP described later). These children, ranging in age from 8 to 18 years, are typically “bland, flat and indifferent during their extensive medical interventions…depressed, socially isolated and often obese.”21 Among the most common presentations are fever without clear etiology, diabetic ketoacidosis, purpura, and recurrent infections. The prognosis is good if identification and psychotherapeutic intervention can be carried out at a young age.21

**Munchausen Syndrome**

The uncommon patient with true Munchausen syndrome has a prolonged pattern of “medical imposture,” usually years in duration. The behavior usually begins before age 20 years and is diagnosed between ages 35 and 39. Twice as many men are affected as women.3,12 Patients’ entire adult lives may consist of trying to gain admission to hospitals and then steadfastly resisting discharge. Their career of imposture usually lasts about 9 years but has continued unabated for as long as 50 years.4 The quest for repeated hospitalizations often takes these patients to numerous and widespread cities, states, and countries.2

These individuals see themselves as important people, or at least related to such persons, and their life events are depicted as exceptional.32 They possess extensive knowledge of medical terminology. Frequently there is a history of genuine disease, and the individual may exhibit objective physical findings.27

The symptoms presented are “limited only by the person’s medical knowledge, sophistication, and imagination.”2 The alleged illnesses involved have been termed dilemmata diagnoses in that investigators rarely can totally rule out the disorder, clarify the cause, or prove that it did not exist at one time.4 Common presentations are those that most reliably result in admission to the hospital, such as abdominal pain, self-injection of a foreign substance, feculent urine, bleeding disorders, hemoptysis, paroxysmal headaches, seizures, shortness of breath, asthma with respiratory failure, chronic pain, acute cardiovascular symptoms (e.g., chest pain, induced hypertension and syncope), renal colic and spurious urolithiasis, fever of unknown origin (hyperpyrexia fictamenta), profound hypoglycemia, and coma with anisocoria.4 Such self-induced conditions themselves may prove highly injurious or even lethal.30

The patient usually presents to the emergency department during evenings or on weekends so as to minimize accessibility to psychiatric consultants, personal physicians, and past medical records.11,27 In teaching institutions these patients typically present in July, shortly after the change in resident house officers.7 They relate their history in a precise, dramatic, even intriguing fashion, embellished with flourishes of pathologic lying and self-aggrandizement. Pseudologica fantastica, or pathologic lying, is a distinctive peculiarity of these patients. In a chronic, often lifelong behavior pattern, the patient typically takes a central and heroic role in these tales, which may function as a way to act out fantasy.35 The history quickly becomes vague and inconsistent, however, when the patient is questioned in detail about medical contacts.2,26 Attempts to manage the complaint on an outpatient basis are adamantly resisted.25 Once admitted, the patient initially appeals to the physician’s qualities of nurturance and omnipotence, lavishing praise on the caregivers. Behavior rapidly evolves, however, as the patient creates havoc on the ward by insisting on excessive attention while ignoring both hospital rules and the prescribed therapeutic regimen.5 When the hoax is uncovered and the patient confronted, fear of rejection abruptly changes into rage against the treating physician, closely followed by departure from the hospital against medical advice.2,10,11,25

**Munchausen Syndrome by Proxy**

The diagnosis of MSBP depends on specific criteria (Box 112-1).14 The presenting complaints typically evade definitive diagnosis and are refractory to conventional therapy for no apparent reason.14 The symptoms are usually more than five in number, presented in a confused picture, are unusual or serious, and, by design, are unverifiable. They invariably occur when the mother is alone with the child or otherwise unobserved.30 In 72 to 95% of cases, simulation or production of illness occurs while the victim is hospitalized.14

Simulated illness, faked by the mother without producing direct harm to the child (e.g., adding blood to a urine specimen), is present in 25% of cases. Produced illness, which the
mother actually inflicts on the child (e.g., injection of feces into an intravenous line), is found in 50% of cases. Both simulated and produced illnesses are found in 25% of cases. Most MSBP cases arise with factitious bleeding, seizures, central nervous system (CNS) depression, apnea, diarrhea, vomiting, fever, and rash. Reported techniques of simulation or production of disease include administration of drugs or toxins (e.g., chronic arsenic poisoning, ipecac, warfarin, phenol, hydrocarbons, salt, imipramine, laxatives, CNS depressants), caustics applied to the skin, and nasal aspiration of cooking oil. Techniques of asphyxiation include (1) covering the mouth or nose with one or both hands, a cloth, or plastic film and (2) inserting the fingers into the back of the mouth. In such instances, even struggling infants may sustain no cutaneous markings. Cases involving seizures are common and may involve third-party witnesses. On personal questioning, however, these witnesses frequently deny the occurrence of seizure activity.

In a variant of MSBP termed serial Munchausen syndrome by proxy, there may be a history of similar strange presentations in multiple siblings, although typically only one child is involved at a time. In 9% of such cases there is a history of siblings who died under mysterious circumstances. Perpetrator Characteristics. Ninety-eight percent of perpetrators are biologic mothers from all socioeconomic groups. Many have a background in health professions or social work, features of Munchausen syndrome themselves, or a past history of psychiatric treatment, marital problems, or suicide attempts. Depression, anxiety, and somatization are common, but frankly psychotic behavior by the mother is atypical. Perpetrators of MSBP have an inherent skill in manipulating health workers and child protection services. They are pleasant, socially adept, cooperative, and appreciative of good medical care. They often display a peculiar eagerness to have invasive procedures performed on their child. They often choose to stay in the hospital with their child, cultivate unusually close relationships with hospital staff, and thrive on the staff’s attention. This affable relationship with the medical team rapidly changes to excessive anger and denial when confronted with suspicions.

Most of these mothers have had an abusive experience early in life, and they use the health care system as a means to satisfy personal nurturing demands. They often cannot distinguish their needs from the child’s and satisfy their own needs first. They derive a sense of purpose from the medical and nursing attention gained when their children are in the hospital. Alternatively, the behavior may enable the mothers to escape from their own physical or psychological illnesses, marital difficulties, or social problems.

Victim Characteristics. Victims of MSBP are equally male and female children. The mean age at diagnosis is 40 months, and the mean duration from the onset of signs and symptoms to diagnosis is 15 months. A known physical illness that explains part of the symptoms is common among these children. Most have a history of significant failure to thrive and have been hospitalized in more than one institution. Delays in many areas of performance and learning, difficulty with family relationships, attention deficit disorder, or clinical depression may coexist. Some of these victims may develop factitious disorder later in life. Victims of MSBP are also found among the elderly population, although this is uncommon.

### Malingering

Malingering is frequently found in association with antisocial personality disorder. On questioning, malingering is vague about prior hospitalizations or treatments. The physicians who previously treated them are usually unavailable. At times, malingering may be careless about their symptoms and abandon them when they believe no one is watching. In some “patients,” such as those seeking drugs, homeless persons seeking hospital admission on a cold night, or prisoners wanting a holiday from incarceration, the secondary gain may be clear. In other persons the external incentive may be obscure.

In contrast to the person with factitious disorders, the malingering prefers counterfeit mental illness because it is objectively difficult to verify or disprove. Amnesia is the most common psychological presentation, followed by paranoia, morbid depression, suicidal ideation, and psychosis.

### Diagnostic Strategies

#### Factitious Disorders

Initial diagnosis is often delayed because the possibility of factitious disease is not considered, physicians may be unfamiliar with this problem, or the patient does not exhibit the type of personality expected with this behavior. Diagnosis may be confounded by genuine medical illnesses predating and coexisting with a factitious disorder. For example, patients with factitious hypoglycemia may have a history of insulin-dependent diabetes mellitus, or factitious skin disorders may be preceded by true dermatologic diseases. Identification of a factitious disorder is usually made in one of four ways: (1) the patient is accidentally discovered in the act, (2) incriminating items are found, (3) laboratory values suggest nonorganic etiology, or (4) the diagnosis is made by exclusion. Wallach provides a useful review of the laboratory diagnosis of factitious disorders including feigned endocrine, hematologic, genitourinary, gastrointestinal, and infectious disorders.

Suspected MSBP requires a detailed description of the event or illness and a search for caregiver witnesses, who should be interviewed personally. Although it is essential to see the child when the symptoms are present, the parents show great ingenuity at frustrating this effort. Additional history of unusual illness in siblings and parents should be sought. Child victims who are verbal should be interviewed in private regarding foods, medicines, and their recollection of the symptoms or events. Prior medical records of the victim and, if possible, the siblings should be examined, although parents may impede such data gathering.

The major obstacle to early discovery of MSBP is its omission from the differential diagnosis. When it is considered, the diagnosis is generally made easily and quickly. A suspected diagnosis may be confirmed through separation of the parent from the child (with consequent cessation of symptoms), covert video surveillance during hospitalization, or toxin screens. In the majority of cases, the caregiver attempts...
to induce episodes surreptitiously while in the hospital, often during the first day of admission. 14,36

Malingering

Malingering should be strongly suspected with any combination of certain factors (Box 112-2). 2,43 A definitive diagnosis of malingering can be established only by securing the patient’s confession, a rare circumstance. 24 Because malingering constitutes criminal behavior, documentation of this diagnosis must be made with care. 20 In the absence of proof of wrongdoing, it is best to assume that the patient is not a malinger but rather a common somatizer. 44 Malingerers who pursue drugs may report an unusually large number of drug allergies to persuade the physician toward prescribing their drug of choice or simply insist on a specific drug (e.g., Demerol or Dilaudid). 45 One unfortunate circumstance of the Internet is the wide availability of quality medical advice on how to convincingly feign pain and disability. 45

DIFFERENTIAL CONSIDERATIONS

Patients with factitious disorders are distinguished from malingerers because their desired hospitalization or surgery seems to offer no secondary gain other than to play the sick role. 2,10,22 The clinical presentation of the majority of patients with factitious disorders, unlike those with Munchausen syndrome, is relatively subtle and convincing. The complaints are generally chronic in nature rather than emergent and precipitous, and there are no obvious associated behavioral aberrations. 71 The most important diagnosis to exclude when faced with a likely factitious disorder is a genuine medical condition that might account for the illness. Malingering is usually associated with less chronicity than factitious disorder, and malingerers are more reluctant to accept expensive, possibly painful, or dangerous tests or surgery. 22

MANAGEMENT

Treatment options for factitious disorders depend on the patient’s characteristics. Although it is challenging, managing common forms of factitious disorder can be more rewarding, especially with adolescents, than managing Munchausen syndrome. 1,9,24,29 Cases stemming from an underlying depression have a more favorable prognosis than those associated with borderline personalities. 57

The best approach to patients with factitious disorder, other than Munchausen syndrome and MSBP, remains an area of controversy. Direct nonaccusatory confrontation has been advocated as “the foundation of effective management” when coupled with the assurance that an ongoing relationship with a physician will be provided. 6,21,22,27 This may be the first step in the acceptance of outpatient therapy. 4

Others point out that confrontation is ineffective in most patients and may even be counterproductive in that it threatens to undermine a needed psychological defense. Enforced recognition of external objective reality, while simultaneously disallowing the patient’s subjective experience, may generate even more dysfunction directed at legitimizing and maintaining symptoms and may even place the patient at risk for suicide. 9,17,29,46,47 Some patients may relinquish this defense if they feel safe in doing so and may abandon a claim to disease if some face-saving option is offered. This approach, termed the therapeutic double bind or contingency management, involves informing the patient that a factitious disorder may exist. The patient is further told that failure to respond fully to medical care would constitute conclusive evidence that the patient’s problem is not organic but rather psychiatric. The problem is therefore reframed or redefined in such a way that (1) symptoms and their resolution are both legitimized and (2) the patient has little choice but to accept and respond to a proposed course of action or seek care elsewhere. 9,47

Individuals with Munchausen syndrome typically demonstrate overt sociopathic traits or a borderline personality disorder and are demanding and manipulative, especially regarding analgesics. 53 They have been described as “essentially untreatable,” and successful management of this condition is, in fact, considered reportable. Early confrontation or limit setting, especially regarding drug use, is advocated. 9,11,21,25,27 Although Munchausen patients typically do not want to be examined extensively, a thorough physical examination should be performed to rule out physical pathology.

MSBP constitutes a form of child (or elder) abuse, and appropriate action to protect the victim, including notification of welfare services, should take immediate priority. 38,41 When the diagnosis has been established and the parents confronted, psychiatric care should be made immediately available to the parents because maternal suicide is a significant risk. 24

Malingerers do not want to be treated. Because they are “gaming the system” for personal advantage, the last thing they want is an accurate identification of their behavior and appropriate intervention. The emergency physician should maintain clinical neutrality, offering the reassurance that the symptoms and examination are not consistent with any serious disease.

Some authors have characterized patients’ use of medical resources under false pretenses as criminal behavior, and several states have enacted legislation against the fraudulent acquisition of medical services. Successful prosecution of such behavior has been reported. 48 Conversely, patients with factitious disorders can and do sue. In dealing with such patients, it is advisable to involve hospital administration and risk management. Clandestine searches are inadvisable, and respect for the patient’s confidentiality should be maintained. 17

DISPOSITION

Patients with factitious disorder should receive primary care follow-up and ongoing care. If acceptable, psychiatric referral should be arranged. Referral to other medical specialists or hospitalization should be avoided when possible.

The manner of presentation and the unavailability of past medical history often allow patients with Munchausen syndrome to achieve hospital admission. If the patient is discharged from the emergency department, outpatient primary care follow-up and psychiatric referral should be offered, although both are likely to be refused. 25

Because perpetrators of MSBP typically induce symptomatic episodes soon after hospitalization, admission of the victims (children or elderly persons) without taking appropri-
ate precautions may actually place them at increased risk.\textsuperscript{14} Visits by the suspected perpetrator should be closely supervised, and no food, drink, or medicines should be brought in by the family. Protective services should be notified. Out-of-home placement of children in established cases of MSBP is advisable, and best outcomes are seen among children taken into long-term care at an early age without access to their mother. Children allowed to return home have a high rate of repeated abuse.\textsuperscript{19} In 20\% of reported deaths, the parents had been confronted and the child sent home to them, subsequently to die.\textsuperscript{14} After courteous but assertive reassurance, suspected malingerers should be offered primary care follow-up if the symptoms do not resolve. These individuals may become threatening when they are either denied treatment or overtly confronted.\textsuperscript{19}

- Emergency department patients who have consciously synthesized symptoms and signs may be divided into two broad diagnostic categories: (1) those with obvious secondary gain (malingering), who control their actions, and (2) those with a motivation of achieving the sick role (factitious disorders), who cannot control their actions.
- Emergency department management of patients suspected of fabricating disease includes a caring attitude and a search for objective clinical evidence of treatable medical or psychiatric illness.
- Unnecessary tests, medications, and hospitalizations should be avoided in the absence of objective evidence of a medical or psychiatric disease, and patients should be referred for ongoing primary care.
- In cases of suspected MSBP involving children or elderly persons, protection of the victim takes first priority.

PERSPECTIVE

Although suicide has occurred in all societies since the beginning of recorded history, attitudes toward suicide have differed dramatically among various eras and cultures. Seneca viewed suicide as the ultimate expression of personal freedom, but later Judeo-Christian religions have routinely condemned it. Shakespeare portrayed suicide sympathetically and expressed either pity or admiration for the victim.\(^1\)

In the United States, suicide is illegal in 49 states, and only since 1994 has assisted suicide of terminally ill patients been sanctioned in Oregon. On the Internet, suicide help groups provide active advice on methods, and numerous bulletin boards condemn them. More than 100,000 sites about suicide now appear on the Internet.\(^2\)

Suicidal patients comprise almost 2% of emergency department (ED) visits.\(^3\) Two facts are especially important to remember when approaching potentially suicidal patients in the ED. First, many suicide attempts occur during an acute crisis, such as a personal loss or the exacerbation of an underlying psychiatric disorder. This acute crisis is usually time limited and may be resolvable or treatable. Second, except for the acutely psychotic patient, suicidal patients are usually ambivalent about dying. The attitude and approach of the emergency physician can help a patient choose crisis resolution rather than death.

Definitions

The term *suicide*, from the Latin *suicidum* (to kill the self), refers to a continuum of thought and action that runs from ideation to completion of the act.\(^4\) *Parasuicide* is used by the British to describe an attempted suicide that is more of a gesture than a serious act. Statistically, there are 10 to 40 suicide attempts for every completed act.\(^5\) *Chronic suicidal behavior* consists of recurrent self-destructive acts, such as heavy drinking in the presence of alcoholic liver disease. *Occult suicide* refers to self-destructive acts disguised as accidents, such as the intoxicated, depressed driver in an apparently accidental car crash. *Silent suicide* describes the act of slowly killing oneself by nonviolent means, such as starvation or noncompliance with essential medical treatment. Silent suicide is most common in elders and frequently goes unrecognized.

A *suicide pact* involves an agreement between two people who are intimately involved and accounts for 0.6% of all suicides.\(^6\) *Mass suicide* or *group suicide* involves a number of willing and sometimes not-so-willing persons, such as members of an apocalyptic cult.

Epidemiology

Suicidal ideation is common, with as many as one in three people considering suicide during their lifetime.\(^7\) Suicide is the eleventh leading cause of death in the United States, claiming more than 32,000 lives annually, with an overall rate of 11.05 per 100,000 population in 2004.\(^8\) This is the equivalent of 89 suicides per day or one suicide every 16 minutes. Over a 5-year period, there were approximately 412,000 annual ED visits for attempted suicide and self-inflicted injury. The most common method of injury was poisoning (68%), followed by cutting or piercing (20%). One third were admitted to the hospital, with 31% going to the intensive care unit. A psychiatric diagnosis was assigned for 55% of visits, with depressive disorder accounting for 34% and alcohol abuse for 16%.\(^9\)

Suicide rates vary with age, gender, race, and marital status. Suicides are highest among older individuals, particularly elderly white men. The case fatality rate also increases tremendously with advancing age, from 5% in youths aged 5 to 14 years, to 34% in adults older than 64 years.\(^10\) White men commit 75% of all suicides in the United States. Whites and Native Americans are much more likely to commit suicide than African Americans, Hispanics, or Asians. Marriage decreases the likelihood of suicide, but separated or divorced people have a higher rate of suicide than those who never had a close relationship.

Women attempt suicide three to four times more often than men, whereas men are three to four times more likely to succeed. In one U.S. study, only 5% of suicide attempts by females were fatal, compared to 23% of those by males.\(^10\) In general, men tend to use more lethal methods, such as firearms. Worldwide, Chinese and Indian women have higher rates of suicide than women of other nationalities.\(^11\) Pregnant women are at a significantly lower risk than women of childbearing age who are not pregnant. Motherhood seems to protect against suicide, except that postpartum depression is associated with a higher than normal suicide rate.

Most people who attempt suicide have one or more known risk factors (Box 113-1). Individuals with the highest risk include those with psychiatric disorders, alcohol or substance abusers, adolescents, elders, and patients with certain chronic illnesses. In patients hospitalized for psychiatric disorders, the first month after discharge carries a high risk of suicide,\(^12\) and
BOX 113-1  RISK FACTORS FOR SUICIDE

Demographics
  White men older than 65 years
  Women older than 60 years
  Males 15 to 24 years old
  American Indian or Native Alaskan 15 to 34 years old

Psychiatric disorders
  Major depression
  Bipolar disorder
  Schizophrenia
  Borderline personality disorder
  Panic disorder

Substance abuse
  Alcoholism
  Drug abuse (especially cocaine)

Medical history
  Prior suicide attempts
  Chronic pain or illness
  Physical or sexual abuse
  Recent psychiatric hospital discharge
  Terminal illness (especially cancer and AIDS)
  Low intelligence scores (in men)
  Lower body mass index
  Short stature (in men)
  Cosmetic breast augmentation (in women)

Family history
  Family violence
  Suicide in family

Social factors
  Firearm in home
  Living alone
  Separated, widowed, or divorced
  Unemployed
  Homeless
  Recent personal loss
  Veterans
  Recent incarceration
  Lack of religious affiliation

Emotional factors
  Hopelessness
  Chronic loneliness
  Fixation on death

that risk is especially great for patients who are in the first week after discharge from a psychiatric facility. Any prior history of suicide, even in the remote past, is an important risk factor.

A strong association may exist between suicide risk and bisexuality or homosexuality in men. This association is also seen in lesbian, gay, and bisexual adolescents. Unemployment appears to be a risk factor for suicide among 18- to 24-year-old men. Homeless people with mental illness are at particularly high risk for suicidal behavior, in part because of the high prevalence of traditional risk factors. Recent incarceration is also a risk factor for suicide. During the first 2 weeks after release, the risk of death among former inmates is more than 12 times that of the general population. The leading causes of death among former inmates include drug overdose, cardiovascular disease, homicide, and suicide. In general, the risk of suicide in recently released prisoners is approaching that seen in recently discharged psychiatric patients.

Suicide completers and suicide attempters represent separate but overlapping populations. Although 10 to 15% of suicide attempters ultimately complete suicide, 60 to 70% of suicide completers have no prior history of attempts and commit suicide on the first known attempt. In individuals who committed suicide while not in contact with mental health services, nearly one third of cases (32%) had no concurrent mental disorder.

PATHOPHYSIOLOGY AND ETIOLOGY
Societal, Psychiatric, and Biologic Factors

There are many motivations for attempting suicide. It may be seen as the only escape from a terminal disease or intense chronic pain. It may be an act of revenge or political protest. Most suicide attempts occur in individuals with intense feelings of hopelessness, guilt, or self-hatred, often compounded by the exacerbation of an underlying psychiatric disorder or by the occurrence or perception of a great personal loss. The underlying causes for suicide are similar for adults and adolescents; however, adolescents tend to romanticize suicide, and "copycat" suicides are frequent after the suicide of celebrities or friends. Regardless of the motivation, most suicide attempters are ambivalent, and their attraction to death is usually counterbalanced by a desire to live. This internal conflict is reflected in the high ratio of attempted to completed suicides, and the fact that most people consult a physician shortly before their death.

Psychoanalysts explain suicide in terms of psychic forces. Freud believed that suicide stems from aggression, initially directed toward another person, which ultimately turns against the self. Depression and suicide in the Freudian model represent internalized anger. Many authorities have recognized this association between aggression and suicide. In the United States, more than 1000 deaths each year result from murder-suicides. The perpetrators are usually depressed mothers, despairing elderly men or young men with intense sexual jealousy. Their victims are usually young children, blood relatives, or female sexual partners. The dual risk for suicide and violence is greatest in alcoholics.

The impulses that lead to suicide differ between violent and nonviolent people. “Suicidality” is correlated with anger, fear, and suspiciousness in violent individuals and with feelings of sadness and despair in nonviolent persons. The psychic roots of suicide may arise from childhood trauma. Chronic loneliness during childhood is associated with subsequent suicide attempts during adolescence, and a history of sexual molestation is linked to suicide attempts in women and adolescents.

Current research suggests a biologic basis for depression and suicide involving the serotonergic and dopaminergic systems. People who attempt suicide have altered serotonin receptor function and low serotonin levels. These abnormalities may be regulated through serotonergic-related genes in persons with major depression. The genetic basis of suicide is not clearly understood. The STin2 genetic locus might, at least in part, account for the observed familial aggregation of suicidal behavior. Polymorphisms in the tryptophan hydroxylase gene may affect the synthesis of serotonin. Recent data also indicate that certain genetic markers may be linked to suicidal ideation associated with medications used to treat depression. The genetic susceptibility to suicide, however, may affect individuals only when associated with psychiatric illness or stress. The rate of suicide is twice as high in families of suicide victims, and a family history of suicide predicts suicide independent of severe mental disorder. Relatives of suicide completers are over 10 times more likely than relatives of comparison subjects to attempt or complete suicide.

Depressed patients who attempt suicide excrete less homovanillic acid in their urine and produce less dopamine.
than depressed patients who have not attempted suicide. Low concentrations of dopamine and serotonin metabolites in the cerebrospinal fluid also correlate with suicidal behavior. Suicide attempts in women vary with estrogen levels, with 42% of attempts occurring during the first week of the menstrual cycle.32

Neuroanatomy may also influence suicidality; suicide victims have smaller right-sided parahippocampi than control subjects.33 Although there are no currently available laboratory tests that can identify individuals at increased risk for suicide, research holds promise for biologic markers in the future.

Some drugs, including reserpine, benzodiazepines, and barbiturates, are associated with depression and suicidal behavior. The Food and Drug Administration recently linked suicidal ideation among children and adolescents to selective serotonin-reuptake inhibitors (SSRIs) and added a black box warning regarding SSRI use for all age groups.34 It is ironic that in both the United States and the Netherlands, SSRI prescriptions for children and adolescents decreased after these regulatory warnings, and that these decreases were associated with increases in suicide rates in both children and adolescents.35

Patients who commit suicide shortly after the initiation of antidepressant medications are explained by the “mobilization of energy” theory.36,37 According to this theory, patients who are profoundly depressed may develop the energy to attempt suicide only as their condition improves with treatment. Such patients must be monitored very closely during their initial phase of treatment.

### Methods of Attempting Suicide

Most completed suicides involve firearms (70%), whereas most attempted suicides involve the ingestion of drugs or poisons (72%).38 In one large study, poisoning with drugs accounted for 74% of acts but only 14% of fatalities; firearms and hanging accounted for only 10% of acts but 67% of fatalities. Firearms were the most lethal means (91% resulted in death), followed by drowning (84%) and hanging (82%).10 Episodes involving firearms are 2.6 times more lethal than the second most lethal suicide method, suffocation.39 In 2005, 17,002 suicides involved firearms in the United States.40 Guns represent the most common method of suicide in all victim subgroups, especially among older persons and adolescents, and the use of guns has increased dramatically in the past decade, recently replacing ingestion as the major cause of suicide among women.41 The simple presence of a gun in the home represents an independent risk factor for firearm-related suicide, but not by nonfirearm means.42 This is particularly true for adolescents, whose risk for suicide increases 5 to 10 times when there is a gun in the household.43,44 In general, firearm prevalence is positively related to the suicide rate, even after controlling for rates of attempted suicide.35 Suicide by handgun is often associated with drug or alcohol use.46 The rate of gun-related suicide is 57 times higher in the first week after purchasing a handgun.47

After gun-related deaths, lethal methods chosen by men tend to include hanging, suffocation, or jumping from a height, whereas women are more likely to commit suicide by poisoning. Antidepressant overdose is the most common cause of suicide by ingestion.48 Cyclic antidepressants are associated with more deaths because of their widespread use and high potential for lethality. Most patients hospitalized for self-poisoning have ingested drugs prescribed by their physicians for depression.49 SSRIs, including fluoxetine (Prozac), sertraline (Zoloft), and paroxetine (Paxil), are less lethal when taken in overdose and have replaced cyclic antidepressants as the first therapy in depression.

The method of suicide depends on many factors, including psychic issues of self-hate, the desire for a peaceful versus violent death, and the availability of fatal means. Those who jump to their death are more likely single, unemployed, or psychotic. Those who use firearms are more likely to be male, alcoholic, to have been arrested, or to have an antisocial or borderline personality disorder.50 Communities with tall buildings and bridges have higher rates of suicide from falls, whereas suicide by gunfire occurs more often in areas where firearms are prevalent.

“Suicide by cop” occurs when a suicidal individual intentionally provokes a police officer by orchestrating a lethal situation where the officer is forced to shoot in self-defense or to protect other civilians. This may account for as many as 11% of officer-involved shootings in Los Angeles.51 Certain individuals carry a suicide note; some offer an eerie postmortem apology to the police officer who ultimately kills them.

### CLINICAL FEATURES

#### Psychiatric Illness

Although most psychiatric patients never attempt suicide, most people who commit suicide have either a diagnosable psychiatric illness or alcoholism. Exceptions include those with mental retardation, dementia, and agoraphobia.32 Patients with an affective disorder, especially major depression, are at highest risk.53,54 Approximately 15 to 20% of people with major depression commit suicide, usually while under psychiatric care.55 Individuals who experience hopelessness, anhedonia (loss of ability to experience pleasure), and mood cycling are at highest risk. Impulsive-aggressive personality disorders and alcohol abuse/dependence are independent predictors of suicide in major depression.56

Approximately 10% of schizophrenic patients will kill themselves. Psychotic patients who commit suicide are most often unmarried whites with high intelligence quotient scores.57 Patients with borderline personality disorders are also predisposed to commit suicide. Women with borderline personality disorder who attempt suicide often have a history of childhood sexual abuse and impulsive behavior. The risk is especially high when patients require hospitalization for psychiatric illness and is greatest the first month after discharge.58,59

Approximately 40% of patients with panic disorder attempt suicide at some point in their lives. These patients usually have an additional comorbid psychiatric diagnosis (e.g., borderline personality disorder, substance abuse, emotional instability). However, any preexisting anxiety disorder (including social phobia, simple phobia, generalized anxiety disorder, panic disorder, agoraphobia, obsessive-compulsive disorder) is an independent risk factor for subsequent suicidal ideation and attempts.50 Post-traumatic stress disorder, sustained by military combat personnel and disaster survivors, is also associated with suicide. Post-traumatic stress disorder frequently coexists with a major depressive episode, and this combined psychopathology enhances the risk for suicidal behavior.51 In 2005, there were at least 6256 suicides among those who served in the U.S. armed forces; a rate double that of nonveterans. Veterans between the ages of 20 and 24 years who served in Iraq or Afghanistan had the highest suicide rate among all veterans.52

#### Alcoholism and Substance Abuse

Of successful suicides reported by the National Violent Death Reporting System, 53.3% tested positive for alcohol, 16.4% for...
Most adolescents who complete suicide are strongly associated with suicide by firearms. Cocaine use is more frequent, repetitiveness, and lethality in suicide attempts than are most other medications. Nearly one half of all adolescents who attempt suicide use drugs shortly before the attempt, and alcohol intoxication is strongly associated with suicide by firearms. Cocaine use is particularly dangerous; in New York City, 20% of all suicide victims younger than 61 years used cocaine within days of their death. Among young Hispanic men, nearly one half of the suicide victims have toxicologic screens positive for cocaine. In general, cocaine abusers choose violent means of self-harm and attempted suicide. Belonging to the "Goth" subculture is a predictor of self-harm and attempted suicide. Gay, lesbian, bisexual, or "not sure" youths may also be more prone to self-harm. Belonging to the "Goth" subculture is a predictor of self-harm and attempted suicide.

Adolescents

Suicide among adolescents has quadrupled during the past 40 years and is now the third leading cause of death (after accidents and homicides) in people between 5 and 24 years of age. Approximately 2 million U.S. adolescents attempt suicide each year, and 19% report serious consideration of suicide in the past year. Although some authorities believe that the rise in adolescent suicide simply corresponds to changing demographics in the United States, others believe that the increase is related to a growing sense of hopelessness, increased economic pressures, and access to firearms. In a survey of high school students in North Carolina, 24% had considered suicide, 19% had planned suicide, and 9% had actually attempted suicide during a 1-year period.

Adolescent girls are more likely to attempt suicide, whereas adolescent boys are more likely to complete suicide; the ratio of attempts to completed suicides is 25:1 for adolescent girls and 3:1 for boys. Most adolescents who complete suicide have made previous suicide threats. The majority of youths who kill themselves meet criteria for diagnosable psychiatric disorders, and both alcohol and substance abuse play a significant role in teenage suicide attempts. Adolescents with panic attacks are twice as likely to make suicide attempts as adolescents without panic attacks. Gay, lesbian, bisexual, or "not sure" youths may also be more prone to self-harm. Belonging to the "Goth" subculture is a predictor of self-harm and attempted suicide.

Nearly 40% of youths in runaway programs report prior suicide attempts. Young people may also be influenced by movies or television shows that feature suicide. Teenage suicides typically increase after television broadcasts on the subject.

From 1989 to 1995, suicide by firearm in young people increased dramatically. The firearm-related suicide rate in U.S. adolescents is 11 times higher than the combined rates of 25 other industrialized countries. Having a gun in the home places the troubled adolescent in great danger, and storing the gun in a locked cabinet or separating it from the ammunition does not deter suicide attempts. Surprisingly, up to 23% of adolescents who have attempted suicide report that their families continue to keep firearms and ammunition in the home despite their suicide attempt.

Older Adults

The highest rates of completed suicide occur in elders. Suicide by firearm is the fourth leading cause of injury-related deaths among older U.S. residents. Older Americans use highly lethal methods when attempting suicide and, unlike adolescents, rarely stage an attempt that permits rescue. Self-inflicted gunshot wounds account for 88% of elder suicides.

White men older than 65 years account for approximately 80% of suicide deaths, whereas suicide is rare among elderly people belonging to minority groups. Suicide among older adults is especially common in those with prior suicide attempts or major depression. Severity of depression is the strongest predictor of suicide in elders. Physicians often overlook signs of depression in older patients, even though most who commit suicide see their primary care physician during the month before their death. In one study, almost half of all elders who committed suicide visited a physician in the preceding week. Elders also have more chronic illnesses that predispose to suicide. Perceived poor health, poor sleep quality, and limited presence of a relative or friend to confide in are also associated with suicide among elders.

Chronic Illness

Patients with terminal illnesses may commit suicide to end their suffering and to reduce the emotional and financial burden on their families. Diseases more highly associated with suicide include cancer, stroke, renal failure, congestive heart failure, and chronic lung disease. In the elderly, congestive heart failure, chronic obstructive lung disease, seizure disorder, urinary incontinence, anxiety disorders, depression, bipolar disorder, and moderate to severe pain are specific illnesses associated with suicide. A history of cancer is an especially strong risk factor in elders.

The acquired immunodeficiency syndrome (AIDS) epidemic has also increased suicide rates, and the relative risk of suicide in men with AIDS is nearly 37 times higher than in uninfected men. Patients who are positive for human immunodeficiency virus but do not have AIDS-defining conditions are more likely to be suicidal than those with active disease.

History

Recognition of Depression and Suicide Potential

Recognition of suicide potential is relatively straightforward in patients who present shortly after a suicide attempt, as well as in individuals who complain of depression or express suicidal ideation during their evaluation. The potential for suicide should also be considered in patients with any acute problem related to chronic alcoholism, substance abuse, or any psychiatric disorder. Silent suicide is possible with patients who present to the ED repeatedly because of noncompliance with treatment of their medical disorders. Occult suicide should be suspected in patients who "unintentionally" overdose or have had "accidental" gunshot wounds, lacerated wrists, automobile crashes, or falls from heights.

Patients Who Present after a Suicide Attempt or Have Suicidal Ideation

Following a suicide attempt, patients with a normal mental status should be queried regarding the specifics of the act after medical evaluation and treatment are initiated. Suicidal patients may give inaccurate histories or may refuse to speak...
to the physician. Because most people who attempt suicide communicate their intent to others at some point, an attempt should be made to interview family, friends, police, and paramedics regarding the patient’s recent actions and possible motivations. They may also provide information regarding the specifics of the current suicide attempt. Although some physicians worry that current federal laws regarding patient privacy conflict with the need to obtain information with the family, an emergency exception to the Health Insurance Portability and Privacy Act rule exists. Section 164.512(j), “Uses and Disclosures to Avert a Serious Threat to Health or Safety,” allows physicians to disclose protected health information without individual authorization “based on a reasonable belief that use or disclosure of the protected health information was necessary to prevent or lessen a serious and imminent threat to health or safety of an individual or of the public.”

Once the patient is medically stable, the presence of risk factors for suicide should be determined. Such factors may include a history of previous suicide attempts or psychiatric care; a history of excessive alcohol or drug use, both acute and long term; family history of suicide; and signs of depression, including a sense of hopelessness. Patients who have a history of deliberate self-harm (self-poisoning, cutting, burning, or hitting oneself) have a higher risk of suicide, especially male patients. Over 5% of people seen at a hospital after self-harm commit suicide within 9 years.

The patient’s marital status and social support are important factors, and the motivation for and the seriousness of the suicide attempt are assessed. Some physicians ask patients to provide their own lists of “reasons why they want to live”—a sort of reverse score for suicidality. If discharge is being considered, patients should be asked whether they would harm themselves if they were released from the ED. Additional demographic information may be helpful (see Box 113-1). The SAD PERSONS mnemonic can be used to document salient points and facilitate subsequent communications with primary care providers and psychiatrists (Table 113-1).

### Patients Suspected of Occult or Silent Suicide Attempts

Patients who are not overtly depressed or suicidal but who exhibit one or more of the high-risk presentations previously described should be assessed in a sympathetic but direct manner using a “graduated” approach. First, rapport should be established during an assessment of the presenting complaint. This should include a general medical and psychiatric history, as well as an evaluation of the patient’s home, work, and social situation, followed by specific questions regarding the signs and symptoms of depression. The emergency physician should ask direct questions regarding suicide, such as, “Have you ever had the thought that life is not worth living?”; “Do you have thoughts of killing yourself now?”; and “What plans, if any, have you made to do this?” Patients who are not depressed or suicidal are generally not offended by this approach, and it does not place the concept of suicide into the mind of someone who has not been considering it. Patients who are depressed or suicidal are often thankful and relieved for the intervention.

## Physical Examination

Patients should be examined closely for evidence of drug ingestion, trauma, or an associated medical illness. Look at the wrists for evidence of prior cutting attempts. The patient’s mental status, vital signs, pupils, skin, and nervous system are helpful in detecting organic conditions, particularly the toxidromes associated with common ingestions (see Chapter 145). Altered mental status should be assessed to determine whether the condition is caused by an organic (medical) or functional (psychiatric) cause (Table 113-2). Physical findings associated with chronic disease, alcoholism, and substance abuse should be sought. The physical examination is often overlooked or performed in a cursory manner in patients with psychiatric complaints. Up to 50% of patients with an acute psychiatric presentation harbor unrecognized medical illnesses.

### Diagnostic Strategies

Routine toxicologic screening tests are unnecessary in the evaluation of suicidal patients. Nearly all patients with dangerous overdoses and poisonings demonstrate clinical signs within several hours of ingestion. An electrolyte panel, while it need not be routine, may be useful in certain ingestions, particularly if an acid-base abnormality is suspected as in salicylate or methanol toxicity. Although the likelihood of potentially lethal acetaminophen ingestion is small in patients who deny taking acetaminophen, the emergency physician should consider measuring the acetaminophen level in patients with intentional overdose. An electrocardiogram should be obtained if cyclic antidepressant overdose is suspected. Patients with acute depression, particularly if newly diagnosed, may need screening tests for underlying medical disorders; however, a

primary care physician or psychiatrist can safely perform this evaluation during follow-up.

■ MANAGEMENT

Out-of-Hospital Care

Out-of-hospital management must focus on the patient’s injuries and potential harm from poisoning or overdose. If the patient refuses to be transported to the hospital or becomes aggressive, emergency medical personnel should involve law enforcement officers. All states give police the right to place individuals into protective custody if they are suspected of being a danger to self or others. The presence of law enforcement officers, or even the threat of calling the police for assistance, usually ensures patient cooperation during transport. Hospitalized psychiatric patients who are transported to the medical facility by police have an independent risk factor for an imminent suicide attempt.99

Emergency Department

The clinical assessment of suicide potential requires an empathetic approach. Patients feel more comfortable discussing personal issues when health care personnel are friendly, non-judgmental, and supportive. Unfortunately, ED staff may be unsympathetic toward patients who attempt suicide because of religious or philosophic beliefs, lack of formal psychiatric training, or inadequate time and personnel to provide appropriate psychiatric evaluation. They may perceive the patient’s behavior as abusive or manipulative and may become frustrated regarding ineffective disposition and follow-up options. Failure to anticipate and overcome these factors can result in inadequate patient assessment and reinforce these patients’ already low self-esteem.

Medical Clearance

The first priority in managing patients is medical stabilization and treatment of injuries, poisoning, or overdose. The second priority is the identification and treatment of associated medical conditions that may underlie a patient’s altered mental status or violent behavior. Patients with significant injury, poisoning, or medical problems should be hospitalized, sometimes in an intensive care setting, where their medical problems can be treated as they remain under constant observation. Five to 40 inpatients commit suicide for every 100,000 hospitalizations.90,91

Suicide Precautions

Most suicide attempts involve minor injury or overdose that can be definitively treated in the ED. Suicidal patients who are calm and cooperative should be placed in an area where they can be safely observed by staff. Having a dedicated “sitter” to watch the patient is helpful and decreases the need for restraints. The sitter should accompany the patient when leaving the area to use the restroom or smoke. No potentially suicidal patient should be allowed to leave the ED before an evaluation is completed. The use of family members as “sitters” is discouraged because they may harm or collude with the suicidal patient to leave or may not intervene if the patient attempts to leave. The use of “wander alert” bracelets, which set off an alarm if a patient wearing one crosses an established threshold may help in monitoring. Security personnel should search all potentially suicidal patients early in the ED stay. Having the patient change into a hospital gown facilitates removal of weapons, medications, and other objects that might be used to inflict injury, such as belts, neckties, and long shoelaces. The patient’s room should be cleared of all potentially harmful objects, including medications, instruments, and glass objects. Suture carts, which may contain scissors, scalpels, or other dangerous objects, must also be kept out of reach. Some rooms designed for psychiatric patients may contain a lockable “pull-down” wall, like those used on storefronts at night, that cover medical equipment and cabinets when a psychiatric patient is in the room.

Use of Restraints

Mechanical and chemical restraint use is based primarily on the physician’s impression regarding the immediate risk of elopement or subsequent suicide attempt as well as personnel available to contain the patient. Some authorities believe that placing a depressed patient in mechanical restraints can impair rapport and contribute to the patient’s diminished self-esteem. Chemical restraints may calm a violent patient but may make subsequent psychiatric evaluation more difficult in the short term.

Nevertheless, restraints may be essential and even lifesaving for uncooperative, violent, or psychotic patients and for those at high risk for elopement or self-harm. The Joint Commission, as well as state and federal government, have stringent requirements regarding the use of restraints. A hospital policy that conforms to these guidelines and an approved and consistently employed restraint flow sheet are important to comply with these regulations. A timed and dated physician order, as well as frequent rechecks of distal neurovascular function, are required for all patients placed in restraints.

Determination of Risk

Once a patient has demonstrated suicidal behavior or ideation, the physician must determine whether the risk is imminent (i.e., within 48 hours), short term (i.e., within days to weeks), or long term.7 The likelihood of an impending repeat attempt will drive disposition: whether psychiatric hospitalization, emergency psychiatric consultation, or discharge and referral for follow-up. One must consider the potential lethality of the method chosen; for example, ingesting a handful of birth control pills is less worrisome than shooting oneself or setting oneself on fire. It is also important to consider if the patient believed the attempt would result in death. Even if the method chosen was nonlethal from a medical standpoint (such as ingestion of antibiotics), but the patient believed it was lethal, the patient may be at risk for a future, more lethal attempt. Patients who plan and hide their suicide attempt may be more desperate to die than someone who makes the attempt in front of a family member who rescues them. In depressed patients, an intense sense of desperation is an important predictor of suicide.93 Another important consideration in the evaluation of the suicidal patient involves the wish to live versus the wish to die. Not surprisingly, those patients with a wish to live are six times less likely to commit suicide than those who wish to die.93

Although one should determine an individual patient’s likelihood for committing suicide if discharged, this assessment is far from exact. No single psychological test can accurately predict suicidal attempts.94 In a group of 4800 psychiatric patients who were followed prospectively over 5 years, 44% of all suicides were not foreseen by the psychiatrist.95 In another group of individuals who completed suicides after evaluation by an emergency psychiatric service, no specific factors could be identified that predicted imminent suicide.96
There are at least 31 different English-language scales devised to predict the risk of suicide, but the vast majority are not designed for or suitable for use in the ED. Some researchers are even using "fuzzy logic" and neural networks to achieve computerized prediction models for suicidality. One study evaluated six clinical suicide assessment scales to identify high-risk patients: the Modified SAD PERSONS scale, revised Beck Depression Inventory, Beck Anxiety Inventory, Beck Hopelessness Scale, Beck Scale for Suicidal Ideation, and the High-Risk Construct Scale. The outcome measured was psychiatric hospitalization admission for suicide risk, not completed suicide or future suicide attempts. All of the scales showed 100% sensitivity and negative predictive value, but lower specificity (38–90%) and positive predictive value (28–71%). Although scoring systems might help in determining the need for hospitalization, they cannot predict future attempts at self-harm. Nevertheless, an attempt to determine a patient’s immediate risk of self-harm should occur and, when indicated, be communicated to other health care providers.

The SAD PERSONS mnemonic provides a “suicide score” and is well suited for use in the ED. Two points are given for each of four high-risk factors: (1) complaints of depression or hopelessness, (2) existence of an organic brain syndrome or acute psychosis, (3) presence of a well-conceived plan or life-threatening presentation, and (4) expression of determination or ambivalence regarding future suicidal behavior. One point is assigned for other important but less significant factors: male gender; age younger than 19 or older than 45 years; a history of previous suicide attempts or psychiatric care; stigmata of chronic alcoholism or substance abuse or the history of recent increased use of these substances; a patient who is separated, divorced, or widowed; and the absence of social support systems, such as close family, friends, job, or active religious affiliation.

A SAD PERSONS score of 6 or more has a sensitivity of 94% and a specificity of 71% compared with formal psychiatric evaluation in identifying the need for hospitalization in patients who present immediately after a suicide attempt. A score of less than 6 has a negative predictive value of 95%. No deaths at 6 to 12 months occurred in patients with low scores. Another risk assessment tool used for adolescents is the Risk of Suicide Questionnaire. The four most useful questions on the Risk of Suicide Questionnaire were the following:

1. Are you here because you tried to hurt yourself?
2. In the past week, have you been having thoughts about killing yourself?
3. Have you ever tried to hurt yourself in the past?
4. Has something very stressful happened to you in the past few weeks?

Any positive answer on this rapid screen correlated with potential risk for self-harm when compared to a longer Suicidal Ideation Questionnaire, but correlation with suicidal outcomes is unknown.

Another simple scoring system is the British Manchester Self-Harm Rule. It uses the following four clinical correlates to determine future risk of suicide attempts:

1. Any history of self-harm
2. Previous psychiatric treatment
3. Benzodiazepine use in this attempt
4. Any current psychiatric treatment

For 9086 patients, any positive answer on the four-question Manchester Self-Harm Rule had a sensitivity of 94% and specificity of 25% for a repeat attempt. Whether this rule would perform as well in a U.S. population with a far greater access to handguns remains unclear.

Suicide assessment should be performed after the patient metabolizes any drugs or alcohol. Intoxicated patients who complain of depression or state ambivalence regarding their future intentions to commit suicide may disavow these feelings once they are sober (but may still be at risk despite the disavowal). In addition, the information obtained from a potentially suicidal patient is best confirmed with a family member or friend as patients who are determined to commit suicide may give false or misleading information.

The crises that precipitate suicide attempts are often time limited, usually lasting from a few hours to a few days. If a crisis has passed or can be adequately addressed, the risk of subsequent suicide is substantially diminished. Hospitalization or emergency psychiatric evaluation should be strongly considered when a patient cannot or will not participate in an evaluation of the current crisis or when the problem is unlikely to be resolved.

Ultimately, the assessment of suicide risk remains a highly individualized process. The crisis that precipitated the suicide event, the patient’s current emotional state, and the presence or absence of a supportive home environment must also be considered. When emergency physicians are uncertain regarding the need for hospitalization, they should err on the side of caution and either admit the patient for psychiatric care or request emergency psychiatric evaluation. A psychiatric social worker or other paraprofessional may assist in gathering information and in making decisions about the need for hospitalization; however, the physician still must make an independent judgment about the patient’s suicide risk. Despite the medical-legal threats involved, nearly a quarter of emergency physicians occasionally send patients with suicidal ideation home without any evaluation by a mental health professional.

Some investigators recommend hospitalization for adolescents who have attempted suicide and cannot be adequately monitored at home. However, discharge to home is an option for those with suicidal thoughts if urgent psychiatric follow-up is arranged and the caregivers can adequately supervise and protect the youth. Discharged adolescents should not be actively suicidal, should not have access to lethal methods, should have a supervising adult to closely monitor them, and should have a mental health evaluation before ED discharge whenever feasible.

### Involuntary Commitment

Many patients who are severely depressed or suicidal will agree to be hospitalized for further evaluation and care; however, others may resist hospitalization. Patients who refuse recommended medical treatment usually do so because of anger or fear. Patients may be angry for being brought to the ED against their wishes or for having to wait for evaluation. Alternatively, they may fear the loss of control associated with hospitalization or the perceived negative stigma associated with a psychiatric disorder. When a patient is reluctant to be hospitalized, the physician should attempt to identify and address the specific concerns. The patient’s family and friends may help convince the patient to accept voluntary hospitalization. Involuntary admission may be necessary if the physician believes the patient may inflict self-harm. Depression alone is not a criterion for involuntary commitment; the accepted legal standard requires the imminent risk of harm to self or others. In some states, even patients who voluntarily agree to hospitalization may need involuntary commitment papers filled out if they are an acute danger to self or others.
Factors for Patients at Low Risk for Suicide

1. Few significant risk factors (e.g., low SAD PERSONS score)
2. Stable and supportive home environment
3. Patient agrees to “no harm” contract and will return to emergency department if situation worsens
4. Family member or friend staying with or available to patient
5. Phone contact with health care provider responsible for follow-up
6. Specific appointment made for follow-up within 24 to 48 hours
7. No gun in home
8. Young female who took a nonlethal ingestion or made “hesitation cuts” to wrists
9. Patient expresses a strong desire to live
KEY CONCEPTS

- Suicide is often provoked by a treatable or reversible short-term crisis.
- Suicidal patients frequently see a physician shortly before their death.
- The most complete information can be elicited with an empathetic approach to the patient and communication with family members, friends, health care providers, and others.
- Suicide precautions in the ED include appropriate use of “sitters” and, when necessary, physical and chemical restraints and involuntary commitment.
- The emergency physician should identify risk factors for suicide, even though determination of suicide risk is not a hard science. The SAD PERSONS score can be of help in documenting this assessment.
- Older men and those who attempt suicide using a firearm are at highest risk for a future completed suicide. Young females, especially those who cut themselves or take a nonlethal ingestion, are generally at lower risk.
- If patients are sent home because their risk of suicide is low, ensure a safe and supportive gun-free environment and early psychiatric follow-up.

Section Nine • Immunologic and Inflammatory

Chapter 114  Arthritis
Bruce D. Adams and Douglas W. Lowery III

Perspective

Socioeconomics

Arthritis and the over 100 related rheumatic diseases represent the leading cause of disability in the Western World. Many of the arthritides, including rheumatoid arthritis (RA), are associated with premature mortality and their treatments often manifest with major toxicity. Because of the tremendous pain and disability associated with joint inflammation, patients with the gamut of arthritic maladies present frequently for emergency evaluation. Up to 25% of all patients with rheumatologic disorders visiting the emergency department (ED) require admission, one third of these to an intensive care unit. There are three reasons to develop a comprehensive approach to patients with arthritis symptoms: to utilize the symptoms as a diagnostic clue to a serious systemic illness (e.g., acute rheumatic fever [ARF], scleroderma, and renal crisis), to evaluate for acute emergencies related to or masked by the disease, and to alleviate acute and chronic pain.

History

Rheumatic diseases (derived from the Greek rheuma, “a substance which flows”) were among the first diseases recognized. Egyptian physicians more than three millennia ago recognized gout, as did Hippocrates in the 5th century BCE (who described other joint ailments, including scleroderma). Podagra, the foot-torturess and offspring of Aphrodite (Venus) and Dionysus (Bacchus), was a bad-tempered virgin who attacked victims after they overindulged to dietary or sexual excess. Roman surgeons under Nero first applied colchicine alkaloids from the meadow saffron (Colchicum autumnale) over 2000 years ago. Sir Thomas Sydenham in the 17th century advanced more scientifically modern descriptions of gout (from which he suffered), but it was his keen observations of ARF, to include his eponymous chorea, that are probably better remembered from the man that first advised modern physicians “primum non nocere.” Dundas proposed the term acute rheumatic fever in 1808 and Trousseau linked the rash of Scarlatina with it in 1873. Its causal relationship with streptococcal infection was finally confirmed in 1900. Similarly, Swediar noted a relationship between urethritis and arthritis in 1784, but the discovery of gonococcal arthritis waited until 1883. Garrod in 1858 coined the term rheumatoid arthritis, although Landre-Beauvais in 1800 and Brodie in 1819 are credited with its early scientific descriptions. Heberden described his “nodes” as early as 1802, and Bouchard described his in 1884, but the entity of osteoarthritis was not clearly defined until 1907. The other connective tissue diseases—systemic lupus erythematosus, systemic sclerosis, and polymyositis—were all described in the middle to late 1880s. Ankylosing spondylitis was first mentioned in 1831 but was not accurately described until the 1930s. The generic term reactive arthritis is now preferred over the eponym of the discredited Nazi war criminal Hans Reiter, who was probably not the first to describe the syndrome.

Did the course of history shift because of this group of rheumatic maladies? Gout, long known as the “disease of kings” because of its predilection for diets of rich foods and alcohol, afflicted emperors throughout the ages. Despite the untreated pain of RA, Presidents Jefferson, Madison, and Franklin Roosevelt succeeded to the extent of being honored on U.S. currency and the artists Renoir and Rubens both painted masterpieces for many years. Some have even theorized that gout led to the fall of the Roman Empire (via its association with lead poisoning) and the rise of the American one (by afflicting its glutinous European colonizers).

Principles of Disease

Anatomy and Physiology

Joints are designed to bear weight and allow motion with as little wear as possible. Three classes of joints are identified: synarthroses (suture lines of the skull), amphiarthroses (fibro-cartilaginous unions of the pubic symphysis and the lower third of the sacroiliac joint), and diarthroses (moving joints). The most common type is the diarthrosis or synovial joint, which consists of two ends of subchondral bone (one convex, one concave) almost completely covered by articular cartilage. The cartilage consists of a matrix of collagen fibers and proteoglycans, which are synthesized by the chondrocytes within it. The cartilaginous surfaces are well lubricated and slide against each other. The joint is surrounded by a capsule that is supported by ligaments, tendons, and muscle and is lined with a synovial membrane (Fig. 114-1).

Cartilage is deformable, compressible, and lubricated by synovial fluid secreted by cells of the synovial membrane lining the joint space. The synovium is up to three cells thick and consists of two cell types: type A cells, which contain lysosomes, and type B cells, which synthesize the fluid. Both types multiply in synovitis and interact with the vasculature to produce arthritis. Joint fluid has a high viscosity because
Figure 114-1. Anatomic structures of the joint with location of selected arthritis diseases. (Redrawn from Goldman: Cecil Medicine, 23rd ed. Copyright © 2007 Saunders, An Imprint of Elsevier.)

of its major component, a polysaccharide, hyaluronic acid. The fluid also contains water, glucose, electrolytes, and proteins of low molecular weight.

Pathophysiology

The disease-specific pathologies are further detailed in the following sections, but the final common pathways of arthritis are initially triggered by trauma, infection, or endogenous cell and humoral inflammatory components. The joint’s metabolic balance then shifts towards catabolic mediators and tissue destruction. The trigger for this inflammatory reaction is different with different diseases. In nongonococcal bacterial arthritis, the cells of the synovial lining phagocytize bacteria. In gout and pseudogout, crystals are released from cells lining the synovium by conditions that precipitate an acute attack. Joint inflammation of the traditional rheumatic diseases has a complex immunologic basis.

Patterns

If the site of the patient’s pain is articular, one must next determine whether the arthritis is monarticular or polyarticular. The arthritis may be symmetrical (e.g., rheumatoid or drug induced) or asymmetrical (e.g., rubella, ARF, or gonococcal). In addition, it may also be migratory (e.g., gonococcal or rubella), subsiding in one area before presenting in another, or additive, remaining in the first joint and progressing to additional joints (Box 114-1).

Distribution

The distribution of joint involvement may give some clues to the disease: the first metatarsophalangeal (MTP) joint is classically affected in gout; the metacarpophalangeal (MP) joints and proximal interphalangeal (PIP) joints in RA; and the distal interphalangeal (DIP) joints and the first carpometacarpal joint in osteoarthritis. Patients with inflammatory arthritis may have low-grade fever, but high fever with chills is more likely
to be caused by septic arthritis. Morning stiffness (gel phenomenon) and improvement of symptoms with activity suggest inflammatory arthritis, while improvement with rest suggests mechanical disorders. Concomitant renal stones suggest gout, genital ulcerations occur in Behçet disease and reactive arthritis, and a purulent urethral discharge suggests gonococcal arthritis or reactive arthritis. The use of isoniazid, procainamide, and hydralazine can precipitate lupus, and thiazides can increase the serum uric acid level, leading to gouty arthritis. Many of the newer RA medicines convey serious potential toxicity.35,36

**Physical Examination**

**General Examination**

A thorough physical examination should be performed that specifically searches for evidence of particular rheumatic diseases. The skin, eyes, and cardiac, pulmonary, and neurologic systems should be examined carefully, searching for systemic manifestations of rheumatic disorders (Table 114-2).

**Joint Examination**

The most important diagnostic tool for evaluating acute arthritis is the examiner’s own hands. Each joint in question should be specifically examined for the following attributes: warmth (the dorsum of the hand can detect a 0.5°C difference); effusion; synovial thickening; deformity; range of motion; pain on actively loaded motion; and tenderness (generalized or localized, articular or periarticular).34,35

**Spine.** When evaluating the spine, the patient should stand, and the vertebral column should be assessed for abnormal curvature or asymmetry. One should perform the Schober maneuver to assess for the limitation of the lumbar spine motion that occurs in ankylosing spondylitis while examining the sacrum and anterior iliac crests to elicit pain in the sacroiliac joints (Fig. 114-2).37

**Hip.** Inflammation affecting the hip joint can be reported by the patient as pain in the anterior thigh, knee, or groin. A hip joint effusion will cause the patient to hold the hip partially flexed. An externally rotated and abducted leg in a neonate strongly suggests infection. Range of motion of the hip is most easily tested by flexing the hip, bending the knee at a
right angle, and rotating the heel medially and laterally to test for external and internal rotation, respectively (Fig. 114-3).

**Knee.** An effusion of the knee joint is relatively easy to detect when it appears as a ballotable fullness medially and laterally. Small effusions can be detected by examining for a transmitted fluid wave. Fullness of the popliteal fossa may indicate a Baker cyst. Passive range of motion may elicit crepitus or clicking. Tibiotalar joint effusions produce swelling under the medial malleolus and make it difficult to palpate the extensor hallucis longus tendon. Tenderness, warmth, and swelling of the great toe MTP joint occur in cases of gout but can also occur with osteoarthritis and RA. Sausage-like swellings of the toes are seen in reactive arthritis.

**Diagnostic Strategies**

**Laboratory Tests**

Laboratory tests other than synovial fluid analysis generally convey only modest diagnostic value in evaluating acute arthritis in the ED.\(^{38-40}\) Three widely used screening tests are a white blood cell (WBC) count, erythrocyte sedimentation rate (ESR), and C-reactive protein (CRP). These values are modestly sensitive but quite nonspecific.\(^{39,41}\) An elevated ESR can be used to screen for inflammatory arthritis when taken into careful clinical context.\(^{39}\) Likewise for CRP with the notable exceptions of scleroderma, polymyositis, and dermatomyositis.\(^{40}\) The ESR is particularly useful when suspecting polymyalgia rheumatica or giant cell arteritis.\(^{40}\) Antistreptolysin O titers or a throat culture provides evidence of antecedent streptococcal infection in ARF. Rheumatoid factor, antinuclear antibody, HLA B27, and other disease specific serologies are generally best deferred to the follow-up physician.\(^{41}\) The serum uric acid level is not helpful in diagnosing acute gouty arthritis because it can actually normalize during the acute phase.\(^{42}\)

**Radiology**

**Plain Radiographs**

Plain radiographs are more helpful in patients with chronic disease than in those with acute arthritis (Box 114-2).\(^{43-45}\) Common findings that help distinguish the different forms of arthritis are set out in Table 114-3.\(^{43}\)

**Computed Tomography, Magnetic Resonance Imaging, and Sonography**

Other radiologic modalities are occasionally performed as part of the workup in an emergency setting. Ultrasonography is useful in evaluating joint effusions and synovitis.\(^{46}\) Computed tomography (CT) detects early sacroiliac joint disease in difficult cases and is the preferred method for evaluating the sternoclavicular joint.\(^{47}\) Sonography, CT, and magnetic resonance imaging (MRI) have been used to evaluate acute hip pain in children to distinguish septic arthritis and transient synovitis.\(^{48}\) MRI is excellent for (1) imaging cruciate ligaments of the knee, (2) detecting early edema in periarticular structures and fluid collection in tendon sheaths, and (3) determining the extent of cartilage destruction.\(^{49}\)
Arthrocentesis

Arthrocentesis is the most important diagnostic modality for evaluating the acutely inflamed joint, especially when considering septic arthritis. Indications and Contraindications

The emergency indications for arthrocentesis in evaluating joint pain include obtaining joint fluid for analysis, draining tense hemarthroses in patients with hemophilia (of the elbows, knees, or ankles and after the appropriate clotting factor replacement), and instilling analgesics and anti-inflammatory agents for the treatment of acute and chronic arthritis. Emergency arthrocentesis is relatively contraindicated with an overlying cellulitis unless the infected area can be avoided during the puncture. Coagulopathy is the other major relative contraindication, but arthrocentesis can be safely performed in the presence of therapeutic levels of warfarin, ideally with a smaller needle. Arthrocentesis of prosthetic joints should only be performed to rule out infection and are best done in consultation with an orthopedic surgeon.

Complications

The primary complications of arthrocentesis are bleeding or infection in the joint space, allergic reaction to anesthetic agents, and long-term corticosteroid-related complications. Dry taps (when no fluid is aspirated after joint puncture) are more common in patients with chronic arthritis owing to obstructing tophi or anatomic abnormalities in the synovium and periarticular tissues. Using a smaller syringe or a larger needle may help in such cases. Even if no synovial fluid is apparent in the syringe barrel after multiple attempts, the capped syringe can be sent for culture analysis and just a single drop from the needle bevel can be used for crystal analysis on a slide mount. An average on the slide of fewer than two WBCs per high-power field predicts a noninflammatory effusion.

Technique

The patient should be positioned comfortably, with adequate exposure and cushioned support for the joint. Muscle tension during the procedure can reduce the joint volume, making the procedure more difficult; thus, every opportunity to provide for the patient’s comfort should be employed. Bony landmarks should be carefully palpated. Under aseptic technique, the skin should be prepared with an appropriate surgical scrub. Adequate local anesthesia can be achieved either by use of a vapor coolant or by local infiltration with anesthetic solution such as 1 or 2% lidocaine. Using an 18- to 22-gauge needle attached to a syringe, the joint space is punctured and aspi -rate the synovial fluid. After aspiration, a long-acting anesthetic can be instilled to alleviate pain, but only if septic arthritis has been excluded can therapeutic steroids be injected.

Synovial Fluid Examination

Analysis of synovial fluid is essential for identifying crystalline and suppurrative causes of acute arthritis (Table 114-4).

Crystal analysis is best performed using polarizing microscopy of a drop of synovial fluid or postcentrifugation sediment placed on a slide with cover slip (Fig. 114-4).45,49,63 Monosodium urate crystals are needle shaped and negatively birefringent (yellow when parallel to the compensator and blue when perpendicular), ranging in size from 2 to 10 μm. Calcium pyrophosphate crystals, in contrast, are polymorphic, rhomboid, and positively birefringent (yellow when perpendicular to the compensator, blue when parallel).49,64 Crystal and septic arthritis can coexist because the infection could actually represent the precipitant of the former.45

Electrocardiography

Electrocardiography is indicated for evaluating a patient with acute arthritis for whom a diagnosis of ARF is being considered.66 Prolongation of the P-R interval is a nonspecific minor Jones criterion, but any number of electrocardiographic findings can manifest.

Differential Considerations

Although certain disease entities (i.e., RA, gonococcal arthritis, Lyme arthritis [LA]) can be placed in several anatomic or temporal categories, the most useful classification of arthritis to guide the differential diagnosis is by chronicity and number of joints involved (see Table 114-1).32,56,68-70 Some rheumatology textbooks include an intermediate category of pauciarticular arthritis or oligoarthritis, but the simpler category system appears to better facilitate care and decision making in the ED.70,71

MANAGEMENT

Descriptive guidelines are provided for the diagnostic strategies for patients with monarticular (Fig. 114-5) and polyarticular (Fig. 114-6) presentations. After a specific diagnosis is made, treatment varies by underlying pathology.

Monarticular Arthritis—Acute

Inflammatory conditions of the periarticular soft tissues such as olecranon bursitis, rotator cuff shoulder tendonitis, and prepatellar bursitis can mimic monarticular arthritis, and classically polyarticular conditions such as RA and the seronegative spondyloarthropathies may present initially in only one joint. The emergency patient with monarticular arthritis should be considered to have septic arthritis until proven otherwise.72,73

Septic Arthritis—Nongonococcal Bacterial

Epidemiology

The incidence of septic arthritis is approximately 2 to 10 cases per 100,000 per year, with an age distribution curve for septic arthritis revealing bimodal peaks for young children and adults over age 55.73-75 Additional risk factors include low socioeconomic status, intravenous drug abuse, alcoholism, diabetes, skin infections, HIV and other immunocompromised states, chronic arthritis (particularly rheumatoid, crystalline, and degenerative osteoarthritis), and following intra-articular corticosteroid injections or prosthetic implants.39,64,56,76-78 Importantly, septic arthritis can occur simultaneously with other forms of arthritis, especially RA and gout.65,79 The diagnosis of...
Figure 114-5. An initial approach to the patient with monarticular arthritis. The majority of diagnoses will be determined by the history and physical examination findings. ANA, antinuclear antibodies; CBC, complete blood cell count; ESR, erythrocyte sedimentation rate; JRA, juvenile rheumatoid arthritis; LFTs, liver function tests; PMNs, polymorphonuclear neutrophils; PT, prothrombin time; PTT, partial thromboplastin time; RA, rheumatoid arthritis; RF, rheumatoid factor; SLE, systemic lupus erythematosus; WBCs, white blood cells. (Adapted from American College of Rheumatology Ad Hoc Committee on Clinical Guidelines: Arthritis Rheum 39:1, 1996.)

Pathophysiology

Any joint, whether native, chronically diseased, or prosthetic, can develop septic arthritis. Bacterial pathogens infect the joint space most commonly by hematogenous spread, but direct inoculation and contiguous spread from bony or soft tissue infections occurs also. Once in the joint, bacteria proliferate essentially unchecked in the highly vascular synovium, which has no limiting basement membrane. This induces an inflammatory cascade, synovial proliferation with neovascularization, and subsequent enzymatic, cellular, and cytokine degradation of articular cartilage. Septic arthritis, unless rapidly recognized and treated, results in serious disabling morbidity with mortality ranging from 5 to 15% or higher.

Microbiology

The microbiology of nongonococcal arthritis has remained fairly constant over time, except for the notable decline of Haemophilus and pneumococcal species in the postimmuniza-
Acute nongonococcal septic arthritis in adults is caused most often by gram-positive organisms (75–90%) followed by gram-negative bacilli (10–20%) and then anaerobes, mycobacterium, fungal and other unusual organisms. Overall, *Staphylococcus aureus* is still the most common cause of septic arthritis, with the rapid emergence of methicillin-resistant strains. *Neisseria gonorrhoeae* accounts for only 20% of cases of all monarticular septic arthritis and more commonly presents with polyarthritis; it is discussed separately. Select populations have higher propensities for specific infecting organisms (Table 114-5).

**Prosthetic Joint Infection**

Prosthetic joint infections are classified as early (<1 month after surgery) or late. The latter can be caused by hematogenous spread or by indolent organisms introduced at surgery that may not surface for up to 1 year. Because the joint is literally replaced, antibiotic bioavailability and host immune response are both impaired in the prosthetic environment. A wide range of culprit organisms have been identified; methicillin-resistant *Staphylococcus aureus* (MRSA) is increasingly prevalent. Arthrocentesis diagnosis of a suspected prosthetic joint infection is best done in consultation with the operating surgeon. A fluid WBC count of greater than 1700/mm³ or a pleocytosis of greater than 65% PMNs is sensitive and specific for infection in this setting.

**Clinical Features**

**Signs and Symptoms.** Classically, septic arthritis presents with fever, joint pain, and effusion, typically in the large joints. Moderate fever occurs in most cases but is typically absent in the presence of immunosuppressive states. Rigors and chills only occur in about 20% of patients. Polyarticular presentation occurs in about 20% of cases, particularly in patients with chronic joint disease and in meningococcal infections. Even in cases of septic polyarthritis, however, the knees are the most common sites of infection.

**Tests.** Laboratory evaluation typically includes complete blood cell count, ESR, and CRP, although they are of marginal discriminatory value. Blood cultures yield the causative organism approximately 50% of the time. Radiographs demonstrate only soft tissue swelling if present; the bony changes of septic arthritis are long-term findings and are not usually present on the initial examination. The only definitive diagnostic test for septic arthritis is arthrocentesis with examination of the synovial fluid. The fluid

WBC count is directly proportional to the probability of a septic joint, but a low WBC count alone should not be used to rule out septic arthritis.\textsuperscript{39,58} Gram’s stain will show bacteria in 50 to 70\% of infected joints.\textsuperscript{61} Synovial fluid cultures for both aerobic and anaerobic organisms should be obtained, ideally by inoculation of pediatric blood culture bottles.\textsuperscript{68,76,77}

Management

The key to successful treatment of septic arthritis is early diagnosis. Substantial delays in diagnosis directly worsen prognosis. Empirical antibiotic therapy should be based on Gram’s stain or the presumptive consideration of likely organisms. Once the diagnosis is made, hospital admission is indicated for administration of intravenous antibiotics and either needle, arthroscopic, or open drainage of the affected joint.\textsuperscript{78,85} In the hospital, daily aspiration to dryness of the joint should be performed, along with irrigation of the joint using a large-bore needle or arthroscopy.\textsuperscript{72} Failure to respond to therapy within a few days, the presence of osteomyelitis, involvement of the hips or shoulders, or involvement of any protheses usually mandates open arthrotomy for drainage. Parenteral narcotic analgesics and immobilization will control pain and discomfort. The antibiotic regimen should initially be based on the Gram’s stain results and then adjusted based on final culture results and sensitivities. For gram-positive organisms, the initial drugs of choice are cefazolin with addition of vancomycin if MRSA is suspected.\textsuperscript{58,68,81} For gram-negative bacilli, therapy should begin with a third-generation cephalosporin, such as ceftriaxone, cefotaxime, or ceftazidime (especially if \textit{Pseudomonas} infection is suspected).\textsuperscript{58,68,81} Antibiotic therapy should continue parenterally for 2 to 4 weeks, depending on the response to therapy, and should be followed with 2 to 6 weeks of oral antibiotic therapy at a high dose.\textsuperscript{61,81}

\textbf{Gonococcal Arthritis}

\textbf{Epidemiology}

Gonococcal arthritis remains the most common form of joint infection in the sexually active population, although it has declined somewhat over the past decade because of the general decline of \textit{N. gonorrhoeae} prevalence, particularly with the more virulent strains.\textsuperscript{82,83} Host risk factors for gonococcal arthritis include pregnancy, menses, and complement deficiency. The 4:1 female predominance may also be explained by mucosal infections more often being asymptomatic in women.\textsuperscript{92}

\textbf{Pathophysiology}

Gonococcal arthritis represents a clinical and pathologic course distinctly different from other bacterial infections and is less likely to create long-term joint pathology.\textsuperscript{59}

\textbf{Clinical Features}

Systemic gonococcal infection complicates 0.5 to 3\% of mucosal infections and presents with two somewhat overlapping musculoskeletal syndromes. The first is a localized septic arthritis, more commonly oligoarthritis than monarthritis, predominantly in the knee, ankle, or wrist. The effusions may be modest. True disseminated gonococcal infection (sometimes termed arthritis-dermatitis syndrome) manifests with bactere mia, diffuse migratory arthralgias, characteristic skin lesions, and tenosynovitis (Fig. 114-7).\textsuperscript{82} A similar syndrome has recently been recognized as a result of \textit{Neisseria meningitidis} infection.\textsuperscript{80}

\textbf{Figure 114-7. Pustular lesion with disseminated gonococcal infection. (From Mandell, Bennett, Dolin: Principles and Practice of Infectious Diseases, 6th ed. © 2005 Churchill Livingstone, An Imprint of Elsevier.)}

\textbf{Management}

Microbiologic diagnosis is problematic because both synovial and blood cultures are positive for gonococcus in no more than 10 to 50\% of cases.\textsuperscript{83} The diagnostic yield is higher when specimens are plated on Thayer-Martin medium and even greater with the use of polymerase chain reaction.\textsuperscript{87} Synovial fluid often yields a positive Gram’s stain and the synovial WBC count tends to be lower than in nongonococcal arthritis (40,000–60,000 cells/mm\textsuperscript{3}).\textsuperscript{81,83} Cervical, urethral, rectal, and pharyngeal cultures are positive in up to 75\% of cases, so all mucosal orifices of the patient (and partner, if possible) should be cultured appropriately.\textsuperscript{82,83} In disseminated gonococcal infection, the skin lesions often contain the gram-negative diplococcus. Treatment should be initiated with parenteral third-generation cephalosporins, such as ceftriaxone, ceftizoxime, or cefotaxime, with transition to oral regimens 24 to 48 hours after clinical improvement.\textsuperscript{82,83} ‘Therapeutic arthrocentesis need not be as aggressive in this form of septic arthritis.’\textsuperscript{84}

\textbf{Gouty Arthritis}

\textbf{Epidemiology}

Acute intercritical gout typically presents in middle-aged men or postmenopausal women, often in the setting of alcohol and dietary binging or acute physiologic stressors such as illness, trauma, or surgery.\textsuperscript{89} Gout risk factors include chronic obesity, hypertension, diabetes, thiazide diuretic or cyclosporine use, radiocontrast and lead exposure, and alcohol or fructose consumption.\textsuperscript{98-100} Purine-rich diets predispose one to gout; such diets include meat, seafood (especially anchovies and shellfish), beer, and legumes.\textsuperscript{95,92} ‘The prevalence of gout appears to be increasing.’\textsuperscript{93} Not all patients with elevated uric acid levels, or even joint crystals, have acute attacks, and many patients with an acute gouty arthritis have a normal uric acid level.\textsuperscript{79}

\textbf{Pathophysiology}

Gout results from inflammation caused by the acute precipitation of uric acid crystals from supersaturated extracellular fluid.\textsuperscript{94-95} Uric acid is a normal metabolic end product of purine metabolism.\textsuperscript{90,96} Hyperuricemia results from its under-excretion in the kidney or, less commonly, from systemic
overproduction (to include inborn errors of metabolism and myeloproliferative diseases). Asymptomatic hyperuricemia typically exists for decades, and less than a quarter of these patients ever develop acute manifestations. During an attack of gouty arthritis, the crystals are ingested by PMNs, resulting in cytokine release and an inflammatory synovial reaction.

Clinical Presentation

Gouty attacks most commonly occur in the great toe MTP joint (podagra, up to 75%), the knee (gonagra), the ankle, and the tarsal joints. Usually only one joint is involved initially, but some patients can experience polyarticular involvement, bursitis, tenosynovitis, or even skin inflammation. The pain is so excruciating at onset that some patients cannot even tolerate the weight of a sheet on the joint. Systemic symptoms range from absent to dramatically mimicking a picture of septic arthritis. Without treatment, the attack is self-limiting, peaking over 24 to 48 hours and lasting about a week. Subsequent attacks tend to get closer together, involve more joints, and last longer, eventually morphing into the final stage of chronic gouty arthritis within a decade. Long-term sequelae include renal stones and tophi in the musculoskeletal units such as the olecranon bursa, Achilles tendon, ulnar surface of the forearm, hands and fingers, knees, feet and toes, and even the helix of the ear. The ED patient may present with a first attack or have a known history of gout with a recurrent episode. Cellulitis and septic arthritis need to be excluded, particularly if the knee is involved.

Diagnostic Tests

Serum uric acid is not helpful in the acute setting because it can be transiently normal, but renal function should be checked. During an acute attack, radiographs of the affected joint will only show soft-tissue swelling, but long-standing disease produces typical asymmetrical bone erosions as a result of crystal deposits, with overhanging margins. The definitive diagnosis of gouty arthritis is made by observing intracellular negative birefringent joint fluid crystals with a polarizing microscope (see Fig. 114-4).

Management

The therapy for gout can be separated into acute treatment and chronic prophylaxis. The latter strategy is not generally an ED consideration except to note that chronic prophyllactic agents such as allopurinol, febuxostat, or probenecid should not be stopped, nor should they be initiated during an acute attack. The goal of therapy is to rapidly resolve the pain and inflammation while avoiding toxicity. Physical modalities such as rest, elevation, and ice are simple and demonstrate modest benefit. Narcotic analgesics and either local or regional anesthetic blocks are potential adjunctive therapy.

The key ED pharmacologic mainstays for acute gout are nonsteroidal anti-inflammatory drugs (NSAIDs; including COX-2-selective agents), corticosteroids (including adrenocorticotropic hormone [ACTH]), and colchicine. Caution should be exercised in using these agents because hypertension, diabetes, and renal and vascular disease are prevalent in this cohort of patients.

NSAIDs. Indomethacin is the most commonly used NSAID for gout at dosages of 75 to 200 mg/day. However, other short half-life NSAIDs at full anti-inflammatory dose are probably as effective. The COX-2 inhibitors such as celecoxib are also alternatives. Relief occurs rapidly over the first 24 hours of NSAID therapy, and duration should continue for another 24 hours after the symptoms abate.

Colchicine. Colchicine inhibits microtubule formation and impedes the inflammatory response to crystals in the joint. Dose recommendations vary, but a reasonable regimen is 0.5 to 0.6 mg orally every 1 to 2 hours until one of three events occurs: the pain is controlled, side effects supervene, or a maximum threshold of three tablets in three hours (or 10 tablets in 24 hours) is reached. All patients will eventually develop gas, nausea, vomiting, or diarrhea from oral colchicine at the higher doses, so many experts recommend lower doses, especially for elders. Colchicine’s effectiveness wanes after about 24 hours, and once a full course of colchicine is given, no more should be used for at least a week. Because it is effective for pseudogout and other crystal arthritides, it cannot be used for diagnostic purposes, although a gratifying therapeutic response does help distinguish crystal arthritis from septic arthritis. Colchicine is contraindicated in patients with hematologic, renal, and hepatic insufficiency.

Adrenocorticotropic Hormone (Corticotropic). Corticotropin is an excellent alternative to the above agents because it acts faster and generally avoids their toxicity in older patients. The dose of ACTH is 40 to 80 IU given intramuscularly. With only a single administration, hypothalamic-pituitary-adrenomedullary axis suppression should not occur.

Pseudogout

Pathophysiology

Calcium pyrophosphate dihydrate deposition disease (CPPD) results when calcium complex crystals form across articular surfaces, manifesting on radiographs as chondrocalcinosis. The pathologic mechanisms are incompletely understood but involve overproduction of chondrocyte pyrophosphate, increased calcium, and histologic changes in the cartilage’s extracellular matrix. CPPD is associated with hemochromatosis, hypothyroidism, hyperparathyroidism, amyloidosis, hypomagnesemia, Wilson’s disease, inflammatory osteoarthritis, and especially aging.

Clinical Presentation

The clinical presentation is very similar to gout and indeed the two conditions may overlap, so synovial diagnosis is important. Pseudogout patients tend to be older and the knee is more commonly involved. Radiographs of the affected joint show the pathognomonic linear chondrocalcinosis (Fig. 114-8), but other radiologic variants are described.
Trauma and Hemarthrosis

Trauma is a common cause of acute monarticular effusion.53,72

MONARTICULAR ARTHRITIS—CHRONIC

Osteoarthritis (Degenerative Joint Disease)

Epidemiology

Osteoarthritis (degenerative joint disease) is the most common form of arthritis in the adult population, especially in elders.125

Pathophysiology

The basic science of osteoarthritis pathophysiology has evolved from a simple hypothesis of mechanical wear and tear to a more complex interaction of multiple molecular pathways that involve mechanical, biochemical, and genetic factors.126 Chondrocytes react to injury by promoting degradative enzymes, growth factors, and cytokines, which can lead to inappropriate repair responses of cartilage, synovial membrane, and subchondral bone.125,127

Clinical Features

The chief complaint in osteoarthritis is pain that worsens with activity and improves with rest.128,129 The absence of systemic symptoms helps distinguish these patients from those with RA. The hands are predominantly affected in some patients with osteoarthritis. Bouchard’s and Heberden’s nodes (osteophyte spurs) are visible and palpable at the PIP and DIP joints, respectively.130 The knee has crepitus on active and passive motion.120 Radiographs of an osteoarthritic joint show asymmetrical joint space narrowing, osteophyte formation at the joint margins, and subchondral cyst formation without osteoporosis.128 The synovial fluid is generally noninflammatory, with fewer than 2000 cells/mm and few PMNs.35

Management

Treatment includes judicious exercise for muscle strengthening, weight loss, relief of muscle spasm, and support for the joint.129,130 Acetaminophen is generally the first-line drug for mild osteoarthritis.112 For more advanced disease, there is a modest efficacy advantage toward NSAIDs and cyclooxygenase-2 inhibitors.129,131 Alternative therapies including glucosamine and chondroitin sulfate have gained popularity, enjoy good safety profiles, and may show symptomatic benefit; however, their effectiveness is still controversial.129,132–134 Capsaicin is a low-toxicity topical agent that may help following a few weeks of therapy.130,134 Intra-articular hyaluronic acid injections for osteoarthritis of the knees provides a modest benefit for some patients.132,135 Intra-articular glucocorticoid injections are reserved for exacerbations of painful osteoarthritis knee effusions and should be given no more than three times annually.129,130,134 Those patients with completely denuded cartilage in the hip and knee may need joint replacement.129,134

POLYARTHRITIS

The differential diagnosis of polyarticular arthritis is much broader than monarticular arthritis. It is helpful to divide polyarticular presentations into two groups. Acute presentations

Basic Calcium Phosphate Hydroxyapatite Crystal Disease

A variant form of crystalline disease results from basic calcium phosphate hydroxyapatite (BCP) deposits.116 BCP deposition in synovial fluid is more difficult to detect with light microscopy and is more rapidly progressive and destructive than pseudogout.115 BCP arthropathy also presents with calcific tendinitis, calcific bursitis, and a “pseudopodagra” of the first MTP in young females.116,120,121 The Milwaukee shoulder syndrome is characterized by severe bilateral osteoarthritis of the glenohumeral joint, rapid destruction of the rotator cuff, and BCP crystals.116,122 Treatment is often ineffective, but steroid injections and physical therapy provide some benefit.116,121

Acute Calcific Periarthritis

A recently recognized form, acute calcific periarthritis results when amorphous calcium hydroxyapatite deposits extravasate into periarticular soft tissue, causing a self-limited, crystal-induced inflammatory reaction.123,124 Usually occurring in women, the symptoms last less than a week and the radiographic findings resolve after about 3 weeks.123

Diagnostic Tests

Joint fluid examination shows the rhomboidal, weakly positive birefringent crystals of CPPD (see Fig. 114-4). As with gout, the patient’s symptoms may mimic septic arthritis, so joint fluid should be Gram stained and cultured.119

Treatment

Treatment for an acute attack is identical to the above therapy for acute gout: NSAIDs, steroids, corticotropin, or oral colchicine (although the latter is not as effective as with gout).113,117,119 Prophylaxis unfortunately is generally less effective because the calcium pyrophosphate crystals cannot be removed.110,114 Treatment of secondary metabolic causes of CPPD, while important, also does not influence the course of the pseudogout.113,116,117

Figure 114-8. Chondrocalcinosis (arrows) in calcium pyrophosphate deposition disease. (From Mettler: Essentials of Radiology, 2nd ed. © 2005 Saunders, An Imprint of Elsevier.)
LA can generally be treated with Amoxicillin and positive B19 antibodies. Concurrent B19-induced aplastic anemia should be excluded, especially in HIV, sickle cell, and other hematology patients.

Viral Arthritis

Viral arthritis typically manifests with acute, self-limited, nondestructive polyarticular arthritis.

Parvovirus

Acute parvovirus B19, the causative agent of pediatric erythema infectiosum, accounts for over 10% of adult acute polyarthritis. This symmetrical polyarthritis resembles acute RA on physical examination, but precipitously follows about a week after a flulike illness with parvovirus. Laboratory diagnosis is supported by a negative or low titer rheumatoid factor and positive B19 antibodies. Concurrent B19-induced aplastic anemia should be excluded, especially in HIV, sickle cell, and other hematology patients.

Rubella

Rubella, once a relatively common form of epidemic arthritis, has declined dramatically since introduction of an effective vaccine. The classic presentation is acute symmetrical polyarthritis, malaise, fever, lymphadenopathy, and maculopapular rash that spreads from the face to the body. A postvaccination syndrome of arthralgia and arthritis occurs commonly, especially in women, from 10 days to several months after immunization.

Hepatitis B and Hepatitis C Viruses

A self-limited acute symmetrical polyarthritis often occurs 2 to 3 weeks before the jaundice phase of hepatitis B virus infection. Musculoskeletal pain frequently accompanies hepatitis C virus infection, ranging from arthralgias, myalgias, and fibromyalgia to cryoglobulinemia and a chronic inflammatory polyarthritis.

Alphaviruses

Several related arboviruses discretely manifest with acute arthritis, fever, rash, and sometimes hemorrhage. Management is generally supportive with NSAIDs, but aspirin should be avoided because of potential hemorrhage. Epidemic febrile polyarthritis occurs throughout the world from viral outbreaks in Sindbis (Scandinavia), Chikungunya (India, Pacific, and South America), O’nyong-nyong (Uganda), and Ross River/ Barmah Forest (South Pacific).

Lyme Disease

Epidemiology

* Borrelia burgdorferi* infection causes the multisystem disorder Lyme disease, the most common vector-borne illness in the Western World. Highly endemic areas in the United States for *B. burgdorferi* and its vector tick *Ixodes* include the Northeast Seaboard, the upper Midwest, and the far West from Northern California to Oregon. Lyme disease follows a prescribed pattern of early disseminated disease (weeks to months after a tick bite) and late disease (from several months to years later). Musculoskeletal manifestations of the early stage primarily consist of migratory myalgias and arthralgias without objective evidence of actual arthritis or effusions. Lyme disease is further described in Chapter 132.

Natural History

When Lyme disease is not treated, 50 to 60% of patients will develop frank arthritis within 6 months, most commonly in large joints, particularly the knees. The natural history of LA is for intermittent episodes gradually abating in intensity and frequency over several years even if untreated. Associated tendinitis or bursitis can occur. LA appears to be autoimmune mediated, rather than a direct result of the spirochetal infection, but early antibiotic therapy clearly reduces its incidence. LA seems to be more prevalent in U.S. infections because its endemic *B. burgdorferi* displays stronger arthritogenic properties than other strains.

Diagnosis

The history of a previous tick bite from an endemic area or the classic erythema migrans rash (although often not remembered by the patient) may aid the clinician in suspecting the diagnosis. Patients have minimal joint pain and usually are afebrile despite large joint effusions. The joint fluid is inflammatory with PMN predominance, but *Borrelia* cannot be cultured from it. The differential diagnosis includes gonococcal arthritis, septic arthritis, ARF, RA, and reactive arthritis. Routine blood testing is nonspecific and unhelpful. Confirmatory diagnosis is by immunoglobulin M and immunoglobulin G serologies, which should be strongly positive at the onset of LA. Immunoglobulin G status will remain positive for an indefinite period despite adequate therapy and resolution of symptoms. Unproven and unreliable urinary antigens are marketed but not recommended.

Treatment

Prophylactic therapy after a tick bite is not generally recommended except for an *Ixodes* attachment of longer than 36 hours in an endemic region; a single doxycycline dose of 200 mg is then sufficient. LA can generally be treated with a 4-week oral course of doxycycline, 100 mg twice daily, Amoxicillin 500 mg three times daily or cefuroxime axetil 500 mg twice daily are acceptable alternatives. Amoxicillin is used instead of doxycycline for pregnant and lactating women and for children under 8 years of age. If Lyme disease is diagnosed at the early stage of erythema migrans, only 2 weeks of treatment is required. More expensive intravenous regimens should be reserved for neurologic or cardiac Lyme disease or refractory LA. Antibiotic refractory LA can be treated with either an intravenous regimen or retreated with an oral regimen of antibiotics, but these prob-
Acute Rheumatic Fever

Epidemiology

ARF is a systemic disease triggered by a complex hyperimmune response to group A streptococcal (GAS) pharyngitis.66,157–159 Host cellular and humoral response to GAS attacks joint, cardiac, and other tissue via molecular mimicry mechanisms.66,160,161 The incidence of ARF has dramatically declined in recent decades. This success is only partly due to the widespread use of antibiotics; improvements in social hygiene and transformation of GAS strains are probably more important factors.66,158,159 However, ARF remains the leading cause of cardiac death among the young in developing countries, and reports of both endemcity and outbreaks in the United States still occur.158,162,163 The highest incidences of ARF (50–500 cases/100,000) occur within indigenous populations of the South Pacific.159,164 The vast majority of cases strike children 5 to 15 years of age.157,159,165

Clinical Diagnosis

The clinical diagnosis of ARF is based on the Jones criteria, which have been updated and revised several times.157,159,166,168 The presence of two major criteria, or one major and two minor criteria, in the presence of laboratory evidence of prior GAS infection is required (Box 114-3). This stratagem is probably moderately insensitive for developing countries where alternate World Health Organization criteria are recommended.158,159,168

Arthritis. Symptoms of ARF generally occur 2 to 3 weeks after an oropharyngeal GAS infection, of which only half are symptomatic.158 Arthritis, typically migratory, occurs in 75% of patients and mostly affects the large joints.157,158 The arthritis last 2 to 3 days in each joint and 2 to 3 weeks overall; the axial skeleton is spared.149 Joints appear modestly inflamed, but the pain is disproportionately excruciating to the patient.157 ARF arthritis responds so dramatically to salicylate or steroid therapy that the diagnosis can become clouded. Lack of response should promote an alternate diagnosis.157 Poststreptococcal reactive arthritis (PSRA) is another sterile GAS-related arthritis recently proposed for patients not fulfilling the Jones criteria for ARF.169,170 The arthritis of PSRA tends to be more additive than migratory, with a lower extremity predominance.131 It typically responds less robustly to salicylates and persists longer than ARF.171

Skin. Erythema marginatum and subcutaneous nodules occur in 1 to 2% of cases.157 Erythema marginatum is manifested by the appearance of well-demarcated, pinkish areas of nonpruritic rash, usually on the trunk, but sometimes spreading to the proximal limbs (Fig. 114-9).

Carditis. Carditis occurs in 50% of patients with ARF and is the most important complication accounting for excess mortality.157–159 The most severe form is a pancarditis that simultaneously attacks the pericardium, myocardium, and endocardium. Endocarditis can be overt, subclinical (detectable only by echocardiography), or transient, with many murmurs regressing after a few weeks of therapy.172 Pericarditis by itself is rare and tamponade even rarer.155 Myocarditis manifests with a host of electrocardiographic abnormalities from prolonged PR interval to atrioventricular blocks.164

Chorea. Sydenham’s chorea occurs in about 10 to 15% of patients with ARF and presents with characteristic facial tics, tremor, weakness, and psychological disturbances.173,174

Laboratory Tests. The laboratory workup for suspected ARF consists of pharyngeal cultures and surveys of antibodies to streptolysin O or anti-DNase B to demonstrate antecedent GAS infection.157,158 The synovial fluid is inflammatory in nature, with an average WBC count of 16,000/mm³, no crystals, and a negative culture.

Management of ARF

Successful management of ARF requires three things: rapid eradication of the GAS infection, prophylaxis against recurrent infection, and the acute treatment of arthritis, carditis, and chorea.157,158,175

Antibiotics. The current recommended treatment of suspected acute GAS infection is benzathine penicillin, 0.6 to 1.2 million U IM or 10 days of oral penicillin (or erythromycin if the patient is penicillin-allergic).157–159,164 Long-term prophylactic treatment to prevent recurrences of ARF is provided with
either oral or parenteral penicillin or erythromycin. The duration of prophylaxis depends on patient age, the presence of cardiac involvement, the number of previous attacks, and other factors.

**General Measures.** Other than antibiotics, ARF treatments were developed well before the era of randomized controlled trials, so their evidentiary basis is suboptimal. Nevertheless, the historic clinical experience with ARF is compelling. Bed rest with gradual mobilization once the initial carditis symptoms have abated has long been a mainstay of therapy. Prednisone therapy may be a more tolerable alternative to aspirin. Prednisone 1 to 2 mg/kg/day slowly tapered after 2 to 4 weeks is generally recommended for patients with acute carditis, and it also alleviates the arthritis and the chorea. Sydenham’s chorea is often self-limited but can be controlled with haloperidol, valproic acid, or carbamazepine.

**Medications.** High-dose aspirin rapidly improves the arthritis and fever, but not the symptoms of carditis. Naprosyn may be a more tolerable alternative to aspirin. Prednisone 1 to 2 mg/kg/day slowly tapered after 2 to 4 weeks is generally recommended for patients with acute carditis, and it also alleviates the arthritis and the chorea. Sydenham’s chorea is often self-limited but can be controlled with haloperidol, valproic acid, or carbamazepine.

**POLYARTHRITIS—CHRONIC**

**Rheumatoid Arthritis**

**Epidemiology and Pathophysiology**

Although RA is a chronic disease, at least 20% of patients have an acute presentation. RA develops in women two to three times more often than in men, with a peak incidence between the fourth and sixth decades of life. There appears to be a genetic predisposition related to the HLA-DR4 haplotype. Immune complexes are formed that stimulate PMNs to release the enzymes that ultimately cause joint destruction. The synovial cells increase dramatically in number and produce even more inflammatory substances. A pannus of granulation tissue is formed that ultimately destroys the joint.

**Clinical Presentation**

Patients commonly see a physician after a prodromal period of fatigue, weakness, and musculoskeletal pain that may last weeks to months. The patient’s joints begin to swell in a symmetrical and additive pattern, particularly the hands (MP and PIP joints), wrists, and elbows. The foot, however, may be the initial site of involvement and is affected in more than 90% of patients with RA, particularly the great and little toe MTP joints. The DIP joints of the fingers are not involved, which helps distinguish RA from osteoarthritis, reactive arthritis, and psoriatic arthritis.

Acute presentations may have only warm, tender, swollen joints that may be difficult to distinguish from a viral arthropathy. Tenosynovitis can occur. Acute pericarditis is not related to the duration of disease and may be an early presentation. In the patient with long-standing RA, long-term changes may be observed. These include MP and PIP swelling, ulnar deviation, swan neck and boutonnière deformities of the hands, and limitation of dorsiflexion of the wrist (Fig. 114-10). The knee is often affected, in the short term with effusion and in the long term with muscle atrophy and Baker cysts. Bursae in the retrocalcaneal region are common complications. Extra-articular complications include subcutaneous nodules (associated with more severe disease), vasculitis of the skin, pulmonary fibrosis, mononeuritis multiplex, and Sjögren’s and Felty’s syndromes. Patients with long-standing RA may have degeneration of the transverse ligaments of the C1-C2 junction, and this requires that precautions be taken during endotracheal intubation.

**Diagnosis**

The workup of the patient in whom RA is suspected should be directed at excluding other causes of arthritis, particularly septic arthritis. Rheumatoid factor, which is an antibody against gamma globulin, is positive in approximately 85% of patients with RA. ESR and C-reactive protein levels may be elevated but are nonspecific and elevated in other rheumatologic diseases.

Early radiographic features of RA are soft tissue swelling and juxta-articular osteoporosis leading to uniform joint space narrowing. Arthrocentesis reveals inflammatory fluid with WBC counts between 4,000 and 50,000/mm³ and more PMNs (75%) than usually seen with crystal disease.

**Management**

Excessive movement increases inflammation, so the initial treatment is rest in combination with anti-inflammatory medication. For early mild disease, many clinicians often still use the salicylates or other NSAIDs, which have gastrointestinal and renal toxicities related to their inhibition of cyclooxygenase. Oral prednisone, 5 to 7.5 mg daily, can effectively control mild inflammation as a bridge to more advanced therapy in early disease. Because the first 12 to 18 months are critical in preventing major joint damage, particularly in aggressive disease, the era of disease-modifying antirheumatic drugs (DMARDs) has emerged. Recent clinical studies support the efficacy of a combination of methotrexate and a tumor necrosis factor blocker in reducing early disease activity. DMARDs are typically prescribed by the consulting rheumatologist, but emergency physicians should be familiar with their potentially life-threatening complications (Table 114-6).

**Adult-Onset Still’s Disease**

Adult-onset Still’s disease (AOSD) is a rare multisystem inflammatory disorder characterized by acute arthritis, characteristic rash, and quotidian or double-quotidian fevers (with the highest temperatures seen in the late afternoon or early evening). The rash is a salmon-colored macular evanescent rash that occurs only with the fever. AOSD’s protean manifestations include sore throat, myalgias, splenomegaly, hepaticitis, and pericarditis. The differential diagnosis includes...
other acute arthritides (especially rheumatic fever) and other causes of “fever of unknown origin.”189 Acute treatment options for AOSD include aspirin, NSAIDs, low-dose corticosteroids, and intravenous gamma globulin.187,190

Relapsing Polychondritis

Relapsing polychondritis, a rare multisystem disorder of unknown etiology, presents with recurrent severe inflammation of joints, sclera, ears, nose, and cardiac and tracheobronchial cartilage.193 Airway compromise, which can be precipitous, is treated with high-dose steroids and sometimes stenting.192,193

Seronegative Spondyloarthropathies

The seronegative spondyloarthropathies share the characteristics of sacroiliac involvement, peripheral inflammatory arthropathy, absence of rheumatoid factor, pathologic changes around the enthesis (ligamentous and tendinous insertion into bone), and a genetic component related to the HLA-B27 marker. The most important of these chronic polyarthritis inflammatory diseases are ankylosing spondylitis, reactive arthritis, psoriatic arthritis, and the arthropathy of inflammatory bowel disease. While some clinical overlap exists, each has its own distinctive features.194

Ankylosing Spondylitis

Clinical Presentation. Patients with ankylosing spondylitis generally have back discomfort with radiologic evidence of sacroiliitis (see Fig. 114-2). There is a male predominance. The classic presentation is chronic, insidious back discomfort of more than 3 months’ duration, with morning stiffness that improves with exercise, in someone under 40 years of age.195 Uveitis is the most common extra-articular manifestation, but life-threatening aortic root disease can rarely occur.195 The peripheral joints are involved in up to 30% of patients with enthesopathic involvement, such as plantar fasciitis and Achilles tendinitis. Radiologically, there is a symmetrical squaring of the margins of the vertebral bodies, and later the development of a “bamboo spine.” MRI changes occur even earlier at the sacroiliac joint.196

Management. The goal of therapy is to control pain, decrease inflammation with NSAIDs, and begin physiotherapy and strengthening exercises.195,197 The new anti-tumor necrosis factor agents also seem to be effective.195,198

Reactive Arthritis (Reiter’s)

Clinical Presentation. Reactive arthritis occurs in genetically susceptible hosts after infection with Chlamydia trachomatis in the genitourinary tract or Salmonella, Shigella, Yersinia, or Campylobacter organisms in the gastrointestinal tract.199 A number of other microorganisms have also been postulated as causative agents.199 Reactive arthritis is generally a disease of young men 15 to 35 years of age in whom arthritis develops 2 to 6 weeks after an episode of urethritis or dysentery. Because cervicitis is often asymptomatic, the diagnosis is more problematic in women. The syndrome is predominantly polyarticular and asymmetrical. The weight-bearing joints of the lower extremities are commonly involved: knees, ankles, and feet, particularly the heels (“lover’s heel”).200 Other physical signs appear early and may be gone when the musculoskeletal complaints persist. Patients may have conjunctivitis early in the disease, which may progress to uveitis.199 Up to 10% of patients have initially painless lesions of the oral mucosa and tongue that later develop into shallow painful ulcers.199 Similar lesions are seen on the glans penis (balanitis circinata), particularly in uncircumcised men (20% of patients). The penile lesions in circumcised men are more psoriatic in appearance. Fingers and toes may swell and appear sausage-like, a phenomenon that also occurs in psoriatic arthritis. In 10% of patients, hyperkeratotic lesions of keratoderma blennorrhagia (waxy plaques) develop on the palms and soles and look like pustular psoriasis. Patients may have inflammation at the insertion of the Achilles tendon, and up to one third of patients have low back pain with limitation of vertebral movement on range of motion.200 Synovial fluid is inflammatory in nature with a predominance of PMNs. Chlamydia, Salmonella, and Yersinia antigens have been found in the synovial membrane and even in the joint fluid, but cultures are sterile. Early x-ray films show an enthesitis where ligaments attach to bone and occurs at the sacroiliac joints, ischial tuberosities, greater trochanter, and Achilles insertion.200 Patients may have a single episode (the mean length of an episode is 4–7 months) or recurrent episodes of arthritis, or a continuous spectrum of disease generally involving the ankles and calcaneus.200

Management. Patients with reactive arthritis respond well to NSAIDs, particularly indomethacin, up to 200 mg/day. Antibiotics improve recovery time for patients with Chlamydia-
triggered reactive arthritis, but not thus far for arthritis with a gastrointestinal cause.\textsuperscript{199}

**Enteropathic Arthritis**

Roughly 10 to 20% of patients with inflammatory bowel disease develop acute migratory, inflammatory polyarthritis of the peripheral joints, especially the knees.\textsuperscript{200,201} Associated inflammatory sacroililitis and spondylitis are more common with males.\textsuperscript{200} The peripheral arthritis generally correlates with flare-ups of the bowel disease, but the spinal manifestations do not.\textsuperscript{200,201}

**Psoriatic Arthritis**

Psoriatic arthropathy occurs in up to 20% of patients with psoriasis. Several forms exist: asymmetrical oligoarthropathy (with sausage digits), symmetrical polyarthropathy, spondylitis (asymmetrical as in reactive arthritis), DIP involvement, and arthritis mutilans (see Fig. 114-10).\textsuperscript{202} Anti-tumor necrosis factor agents show promise for its treatment.\textsuperscript{203}

**Fibromyalgia**

**Emergency Department Considerations**

Patients with fibromyalgia commonly present to the ED with diffuse musculoskeletal pain.\textsuperscript{204} The encounter is typically unpleasant for both the patient and the physician because the disease is ill-defined, there may be suspicion of analgesic abuse, and psychiatric comorbidity is common.\textsuperscript{204} Current thinking regarding the pathophysiology of this disorder hypothesizes that the patients process normal pain stimuli aberrantly.\textsuperscript{205} Patients with fibromyalgia have a history of idiopathic widespread pain (bilateral, upper and lower body, and spine) and an examination showing excessive tenderness of 11 of 18 specific muscle-tendon sites. The differential diagnosis includes the other rheumatic diseases, hypothyroidism, and depression.\textsuperscript{205}

**Management.** Treatment of fibromyalgia in the ED includes ruling out associated disease, relieving acute pain with anti-inflammatory medications, providing empathy and education, and referring the patient to a provider experienced in chronic pain management.\textsuperscript{206} For patients in significant distress, the combination of tramadol 75 mg four times daily in combination with acetaminophen may give relief.\textsuperscript{207} Selective serotonin reuptake inhibitors or low-dose tricyclic antidepressants improve both sleep and pain measures in patients with fibromyalgia.\textsuperscript{205,206,209}

**Polymyalgia Rheumatica**

Polymyalgia rheumatica presents with musculoskeletal aching and morning stiffness, especially of the shoulder and pelvic girdle, generally in persons over age 50 years.\textsuperscript{210,211} The ESR should exceed 50 mm/hr, but physical examination signs are modest.\textsuperscript{210} Patients usually respond to low-dose prednisone (10 mg/day) and should be referred for evaluation for giant cell arteritis, a closely associated disorder.\textsuperscript{210}

**Scleroderma (Systemic Sclerosis)**

Musculoskeletal manifestations of scleroderma include morning stiffness, generalized arthralgia, sclerodactyly, and Raynaud's phenomenon.\textsuperscript{212} Scleroderma renal crisis is the most feared emergent complication.\textsuperscript{213}

**DISPOSITION**

The major challenge in the emergency management of acute arthritis is ruling out septic causes. If a patient is diagnosed with nongonococcal septic arthritis based on a positive Gram's stain or culture, or based on strong clinical suspicion even in the face of a negative Gram's stain, the patient should be admitted with emergency orthopedic consultation for parenteral antibiotics and evaluation for possible arthroscopy or arthrotomy. Patients in whom a disseminated gonococcal infection is suspected should be admitted for parenteral antibiotics and orthopedic consultation, except in cases in which the patient is well-appearing, the symptomatology is mild, and the patient is able to comply with the daily follow-up plans. Patients with noninfectious causes of arthritis can be discharged, assuming their pain is controlled and appropriate follow-up is arranged.

---

**KEY CONCEPTS**

- The most likely cause of acute arthritis can usually be identified by considering the time course (greater or less than 6 weeks’ duration), the number of joints involved (monarticular vs. polyarticular), and the distribution of joint involvement (large vs. small joints and symmetrical vs. asymmetrical joint involvement).
- The possibility of septic arthritis should be considered in all patients who present with monarticular arthritis.
- The most definitive test for evaluating an inflamed joint for the possibility of bacterial infection is synovial fluid analysis. Delays in the diagnosis and treatment of septic arthritis worsen outcomes.
- A negative Gram’s stain of synovial fluid does not rule out bacterial arthritis.

CHAPTER 115  Tendinopathy and Bursitis

Michael J. Schmidt and Stephen L. Adams

TENDINOPATHY

Perspective
Diseases of rheumatism have long been of concern to physicians, with evidence that many of Hippocrates’ aphorisms made reference to such ailments. In the mid-1600s, Sydenham, a physician who had gout, described gout, acute rheumatism, and Sydenham’s chorea and hence began to identify distinctions among various processes of musculoskeletal complaints and joint inflammations.1 Today, given the increased participation of people in athletics and fitness, the emergency physician may see a wide variety of patients with tendinopathies due to overuse and injury.2 Approximately half of all sports participants will be injured at some time, and of these injuries, up to one half will involve a tendinopathy. Among athletes, studies have indicated that tendinopathies have been involved in approximately 30% of running-related injuries and in nearly 40% of tennis injuries.1,3 In the workplace, the incidence of work-related musculoskeletal disorders is higher in occupations that involve repetitive motion, localized contact stress, awkward positions, vibrations, and forceful exertion. Studies have demonstrated that improvements in ergonomic design can reduce the incidence of tendinopathies.3

Complicating the acute pain and functional limitations, tendinopathies often become chronic and can be disabling. Patients may have symptoms for extended periods of time despite appropriate therapy.4 The management of tendinopathy focuses on identification of the cause of discomfort; elimination of sources of primary tendinopathy; institution of treatment modalities such as analgesic medication, protection, relative rest, application of ice, compression, and elevation as necessary; modification of behavior to minimize or eliminate sources of continuing irritation; and, importantly, referral for appropriate follow-up care.4

Principles of Disease
Tendons are collagenous structures that connect muscle to bone. They transmit the forces originating in the muscle to the bone, which enables joint motion.5 The diagnosis of tendinitis, a commonly used term implying an “inflammation of the tendon,” has long been attached to many overuse injuries.5 Many practitioners now advocate use of the term tendinosis as a more accurate reflection of the pathologic process, given that histologic findings consistent with inflammation are not clearly evident in pathoanatomic studies.6 Although it has been noted that reliable, well-conducted epidemiologic studies have not been performed for most tendinopathies, the histopathologic substratum, in many cases, is degenerative.5 The term tendinopathy is used throughout this chapter to refer to the impaired tendon, as it encompasses the variety of pathologies.5

Mechanical overload and repetitive microtrauma to the musculotendinous unit are thought to be the major precipitating causes of most tendinopathies. This is a result of intrinsic and extrinsic factors that modify the pathophysiologic state.5,6 Intrinsic factors, such as malalignment, poor muscle flexibility, muscle weakness, or imbalance, can result in excessively high or frequent mechanical loads during normal activity. Extrinsic factors, such as poor ergonomic design or excessive duration, frequency, or intensity of activity, can also contribute to the development of a tendinopathy. Many injuries have a multifactorial origin. Individual factors can contribute as well. For example, a young athlete may develop a tendinopathy as a result of mechanical overload on the basis of repetitive exercise and poor technique, whereas an older athlete with previously occult underlying tendon degeneration and decreased vascularity may see the symptoms of a tendinopathy develop with minimal exercise.7 An increased incidence of tendinopathy and tendon rupture, particularly of the Achilles tendon, is reported in patients taking fluoroquinolone antibiotics, particularly in individuals older than 60 years who are receiving steroid treatment.8

Under optimal conditions, such as appropriate athletic training, the musculotendinous units are able to adapt to tension overload because of the ability of bone to increase its load-bearing capacity and due to an increase in size and strength by hypertrophy of existing muscle fibers. An enhancement of tendon and ligament strength occurs by an increase in collagen content, collagen cross-linking, and mucopolysaccharide content.6 Unfortunately, many athletes may not allot sufficient time for this adaptive process to occur. For instance, a runner may increase mileage, intensity, or both with excessive alacrity, not allowing time for the cellular changes that are required to adapt to the increased stresses. Poor technique and improper equipment may also contribute to the development of an overuse syndrome.9

As the damaged tendon goes through several stages in the healing process, it may take 6 to 12 weeks for structural organization and collagen cross-linking to return the tendon to its preinjured strength.9 As the healing process ensues, unrestricted activity is generally avoided. However, atrophy associated with immobilization should also be avoided because the strength in healing tendons...
and ligaments increases faster when controlled forces are applied. Consequently, flexibility forces, isometric contractions, and a measured return to resistive exercises have been suggested as long as pain is not produced. In summary, a prescription for good follow-up with proper rehabilitation is important in caring for the patient with tendinopathy.

Some areas with common presentations of tendinopathies are diagrammed in Figure 115-1.

**Clinical Features**

**History**

The history of the patient presenting with a tendinopathy can be quite variable, although certain clinical aspects are characteristic. A recent history of repetitive stress may be obtained by inquiring about changes in sports or other recreational activities, work activities, or changes in the workplace. Many patients initially report no such changes, but when prompted to consider activities over several weeks or months (including sports equipment utilized, workplace ergonomic features, protective boots, or other features), a potential inciting change or activity may be elicited. Occasionally, no cause is identified for an inciting mechanical overload. A history of infectious disease, fluoroquinolone therapy, or other systemic illness should also be obtained.

Pain is the most common symptom of the patient who presents with tendinopathy. Increasing discomfort, nonradiating, at the site of the affected tendon is a general symptom. The discomfort is frequently described as more severe subsequent to periods of rest. Unlike the discomfort of morning stiffness associated with arthritis, the pain of tendinopathy may resolve after initial movement, only to manifest itself as a throbbing pain after completion of exercise. The patient may have had prior similar episodes. Continued episodes may be accompanied by an increased severity in pain. Consequently, it may be helpful to know whether a diagnosis was made (and how) and which treatment rendered (if any) was successful.

**Physical Examination**

In the evaluation of the patient with a tendinopathy, a thorough, directed musculoskeletal examination yields important information. Inspection searching for signs of edema, effusion, erythema, atrophy, deformity, symmetry, or trauma can be helpful. Palpation of the tendon, noting warmth or evidence of crepitation on movement, is important. Evidence of tenderness over the tendon, especially localized, reproducing the patient’s pain should be elicited. Underlying bony tenderness (and consideration of other differential diagnoses, including avulsion fracture and osteomyelitis) should be assessed as well. Motor evaluation, particularly passive and active range of

---

Figure 115-1. Location of common sites for tendinopathy or bursitis. (Modified from Branch WT: Office Practice of Medicine, 2nd ed. Philadelphia, WB Saunders, 1987.)
motion (and symptoms elicited during the examination), strength (and evidence of weakness or pain), and joint involvement and stability should be noted.

In narrowing the diagnosis, it is important to determine whether the source of pain is articular (within the joint capsule) or periarticular (around the joint capsule). In general, arthritis produces generalized joint pain, warmth, swelling, and tenderness. The discomfort of arthritis increases with both passive and active motion of the joint. In contrast, the pain of a tendinopathy tends to be more localized. Tenderness and swelling do not occur uniformly across the joint, and pain may be produced only with certain movements, most commonly with resisted active contraction or passive stretching of the affected muscles or tendons.

### Specific Tendinopathies

#### Shoulder

Tendinopathies of the shoulder joint include impingement syndrome, which includes subacromial bursitis or rotator cuff tendinopathy, bicipital tendinopathy, calcific tendinopathy, and adhesive capsulitis. Impingement Syndrome and Rotator Cuff Tendinopathies. The shoulder joint is predisposed to soft tissue injury because of its extensive range of motion and unique anatomic structure. Although inherently unstable, the muscles of the rotator cuff (supraspinatus, infraspinatus, teres minor, and subscapularis) and the glenohumeral ligaments serve to stabilize the joint. The muscles of the rotator cuff originate from the scapula (hence their nomenclature), and their tendinous insertion is found on the fibrous capsule of the glenohumeral joint after traversing the subacromial space. The presence of the subacromial bursa, as for all bursae, serves to ensure fluidity of movement but it may become inflamed as a part of an impingement syndrome. Impingement of the tendons occurs because of their unique position interposed between the humeral head and the acromion, which may predispose to a chronic tendinopathy. The functional arc of the elevated shoulder is forward and in the anterior plane. As a result of this position, the greater tuberosity of the humerus may compress (impinge) the tendons of the rotator cuff (usually the supraspinatus) against the undersurface of the anterior third of the acromion. Because of the insertion of the tendon of the long head of the biceps, it too may be involved as part of the impingement syndrome. Development of this tendinopathy may be a result of overuse of the extremity that leads to microtrauma of the tendinous fibers or due to individual anatomic differences (congenital or from the process of aging, such as osteophytic changes) that predispose to tendinopathy, or both. Other entities that may coexist and complicate an impingement syndrome include subacromial bursitis, bicipital tendinopathy, and calcific tendinopathy.

More than 30 years ago, Neer noted that 95% of rotator cuff tears are associated with impingement (excluding tears due to a one-time traumatic event). He described three progressive stages of the impingement syndrome as a result of overuse. The first stage is frequently seen in athletes younger than 25 years who participate in sports that require repetitive overhead motions of the shoulder (e.g., swimming and baseball). It is characterized by edema and hemorrhage within and around the tendon. The pain is usually described as a dull ache over the anterolateral shoulder, extending from the shoulder to the middle upper arm, often occurring after an activity involving flexion and abduction of the arm. Point tenderness may be elicited over the greater tuberosity. No weakness or loss of motion is generally present. This condition is generally believed to be reversible with appropriate treatment. In the second stage, as mechanical trauma continues, fibrosis and thickening of the tendon and subacromial bursa can occur. This generally affects patients between 25 and 40 years of age. The pain becomes constant and may worsen at night. Active motion may be limited by pain, and any activity involving overhead movement exacerbates the symptoms. Passive range of motion should be preserved, and on physical examination, pain is more diffuse and intense. The third stage has symptoms similar to those of the second stage but may involve a prolonged history of shoulder problems. The range of motion of the shoulder is usually decreased due to either disuse or a partial rotator cuff tear. Pathologically, tendon degeneration and attrition may be present. Partial-thickness tears may occur or extend with minor trauma or stress. Complete tears of the rotator cuff, biceps tendon rupture, and osteophytic bony changes are sometimes seen.

Physical examination in the evaluation of a rotator cuff tendinopathy includes maneuvers that can exacerbate the symptoms of impingement. Because the supraspinatus tendon is most often involved, a physical examination sign (sometimes referred to as Jobe’s sign, after Dr. Frank Jobe, team physician of the Los Angeles Dodgers, or the empty can test, describing the position of emptying aluminum cans) is helpful in assessing the supraspinatus tendon with resistance testing. With the arms abducted at 90 degrees in the scapular plane (30 degrees anterior to the coronal plane), the arms are internally rotated with the thumbs pointed downward. The examiner places a downward force on the arms, and the patient is instructed to resist the examiner and keep the arms parallel to the floor. Weakness or pain would be considered a positive finding. If the patient is unable to resist the force of the examiner, supraspinatus weakness should be suspected. Another sign of rotator cuff tendinopathy is the Neer test, which suggests mechanical impingement with decrease of the subacromial space. The examiner forward-flexes the arm, which causes impingement of the greater tuberosity of the humerus with the anterior and inferior edge of the acromion. The patient’s shoulder should then be fully flexed to 180 degrees. A positive result occurs if there is pain produced at the end range of the arc.

The Hawkins test, also indicative of mechanical impingement, is performed by forcibly internally rotating the proximal humerus while the shoulder is forward-flexed to 90 degrees and the elbow flexed to 90 degrees. Pain with this maneuver indicates a positive finding. A sign of complete rotator cuff tear is the drop arm test, in which the arm is passively abducted at 90 degrees and the patient is asked to maintain the abduction. If the arm drops to the side, a large rotator cuff tear must be considered. The shrug sign is exhibited when a patient with acute macrotrauma to the rotator cuff is asked to abduct the arm at 90 degrees and appears to be giving a shrug with that side. This movement results from the scapula attempting to abduct the arm without the assistance of the rotator cuff. Patients with adhesive capsulitis (frozen shoulder) have limitation of active and passive range of motion.

#### Bicipital Tendinopathy

The tendon of the long head of the biceps, given its insertion into the humerus in proximity to the rotator cuff, can be associated with the impingement syndrome. The patient with bicipital tendinopathy may report pain in the anterior shoulder that radiates down to the radius. Discomfort occurs when rolling on the shoulder at night or when attempting to reach a hip pocket or a back zipper. Focal tenderness can be obtained by palpation in the groove between the greater and lesser tuberosities of the humerus while testing for Yergason’s sign, which is elicited by having the patient flex
the elbow to 90 degrees with the arm against the body and resisting supination of the forearm. Pain in the area of the proximal tendon is considered to be a positive finding and indicative of bicipital tendinopathy.19,22

Another physical examination tool in the diagnosis of bicipital tendinopathy is the Speed test. With the elbow extended and the forearm supinated, the patient is instructed to resist forward flexion of the adducted shoulder at 60 degrees. Pain in the area of the proximal biceps tendon (bicipital groove) is indicative of a positive finding. (This may also be suggestive, however, of labral pathology.) 19

**Calcific Tendinopathy.** Calcific tendinopathy is an aptly named condition in which the deposition of calcium hydroxyapatite crystals occurs in or around the tendons of the rotator cuff. The cause is unknown but has been postulated to be related to chronic microtrauma. It can manifest as either an acute or a chronically painful condition. Although it can affect any of the rotator cuff tendons, it seems to have a predilection for the supraspinatus. The symptoms are similar to those of an impingement syndrome, and the condition generally affects people older than 40 years. Calcium deposition occurs over time and then undergoes spontaneous resorption. This resorptive phase is thought to be the painful aspect, but the severity of the symptoms is not related to the size of the deposit. Some practitioners have suggested that acute attacks of calcific tendinopathy also occur secondary to crystal release from the tendon, often after trauma.25

On physical examination, there may be specific tenderness over the greater tuberosity as well as symptoms consistent with impingement. Radiographic evaluation will confirm evidence of calcification in or around the rotator cuff tendons. The presence of calcium in the tendon does not necessarily affirm the origin of the pain because asymptomatic patients may have evidence of calcification on a routine radiograph.26

**Elbow**

Increasingly, athletes of all ages and skill levels are participating in sports involving overhead arm motions; consequently, elbow injuries are increasingly seen. From an anatomic and functional perspective, the extensors and supinators of the wrist attach to the lateral elbow, and the flexors and pronators attach medially.

**Lateral Epicondylitis.** Lateral epicondylitis (“tennis elbow”) is a painful elbow condition that occurs at the insertion of the common extensor tendon (extensor carpi radialis brevis) onto the lateral epicondyle of the humerus. Although it occurs in many tennis players, epidemiologic studies suggest that fewer than 5% of patients with such a syndrome actually play tennis. Activities such as driving in screws, use of a wrench, and repetitive work on an assembly line have also been implicated. Symptoms often begin as a dull ache on the outer (lateral) aspect of the elbow.21,25,26 The discomfort can be exacerbated by activities that involve extension or supination of the wrist, such as grasping and twisting. The Cozen test is performed by having the patient keep the fist clenched while extending the wrist. The examiner grasps the forearm with the left hand while the right hand pulls the patient’s hand toward flexion against the patient’s resistance. A positive finding is pain at the lateral epicondyle, reproducing the patient’s symptoms.29

Active extension of the long finger against resistance with the elbow in extension can also reproduce the pain over the lateral epicondyle at the insertion of the extensor carpi radialis brevis. A similar sign, referred to as “the finger-snapping test,” is characteristic for an enthesopathy of the extensor carpi radialis brevis. If the test is negative, it is assumed that the pain is caused by spondylogenic, arthrogenic, or neurogenic phenomena.30

Radiographs can be helpful in cases with atypical or prolonged symptoms and to rule out other pathologic conditions. Approximately 20% of patients demonstrate tendon calcification or a reactive exostosis at the tip of the epicondyle.28

The differential diagnosis of lateral epicondylitis includes posterior interosseous nerve entrapment (motor aspect of radial nerve in forearm). Other associated lesions include plica, synovitis, chondromalacia, and adolescent osteochondral defect.28

**Medial Epicondylitis.** The pain of the less common medial epicondylitis (“pitcher’s elbow” or “golfer’s elbow”) can result from microtrauma at the site of the insertion of the flexor carpi radialis on the medial epicondyle. It is important to differentiate medial epicondylitis from other causes of medial elbow pain, including medial ulnar collateral ligament injury. As a result of repetitive valgus stress placed on the joint, microtraumatic injury and valgus instability at the ligament can occur. With disruption of the medial ulnar collateral ligament, abnormal stress is placed on the articular surfaces, which may lead to degenerative changes and the formation of osteophytes.27,31

In the case of medial epicondylitis, patients will generally have tenderness over the flexor-pronator origin slightly distal and anterior to the medial epicondyle. Pain can be reproduced by having the patient attempt wrist flexion and forearm pronation against resistance.32

**Wrist**

**De Quervain’s Tenosynovitis.** The wrist and hand comprise several tendons that pass through thick, fibrous retinacular tunnels. These help prevent subluxation of the tendons and act as a pulley system. Overuse syndromes are thought to result from changes of the synovial lining between these tendons and retinaculum. De Quervain’s tenosynovitis involves the synovial lining of the abductor pollicis longus and extensor pollicis brevis. Although the term tenosynovitis indicates an inflammation of the tendon sheath, it has been noted that there are many potential forms of tenosynovitis. Classic acute inflammatory changes that are characteristic of tenosynovitis may be related to systemic manifestations of disease (e.g., rheumatoid arthritis and gout); tenosynovitis related to de Quervain’s syndrome is referred to by some practitioners as stenosing tenosynovitis. The pathology of de Quervain’s tenosynovitis does not generally involve inflammation because the primary pathologic change seen is thickening of the extensor retinaculum covering the first dorsal compartment of the wrist. It has been suggested that de Quervain’s disease is a result of intrinsic degenerative mechanisms rather than extrinsic inflammatory ones.33

The history may consist of chronic, repetitive trauma or unaccustomed repetitive efforts such as firm grasping and movement of the hand in a radial direction. Direct trauma, such as a direct blow or fall, has occasionally been implicated.34

The discomfort of de Quervain’s tenosynovitis can be localized over the radial styloid process. Radiation of pain proximally to the forearm or distally down the thumb has been noted. The pain is generally constant but may be exacerbated by maneuvers that include grasping, abduction of the thumb, and ulnar deviation of the wrist. In many cases of De Quervain’s tenosynovitis, the onset is gradual and not associated with a history of acute trauma.34

On physical examination, slight swelling may be seen over the radial styloid. Crepitation may be palpable over the tendons with flexion and extension of the thumb. An increase in the tensile load (passive stretching or active contraction) in the abductor pollicis longus or extensor pollicis brevis increases
The differential diagnosis includes scaphoid fracture and osteoarthritis of the carpometacarpal joint, which has pain caused by longitudinal traction and compression. Tuberculous tenosynovitis can manifest with a tenosynovitis of the extensor tendon of the thumb, and gonococcal tenosynovitis has been reported as an extensor tenosynovitis as well.

**Knee**

**Patellar Tendinopathy.** Patellar tendinopathy or “jumper’s knee” occurs in sports that have jumping as a part of the activity, although it can also occur as a result of other sporting activities. Patients complain of pain at the inferior pole of the patella. The discomfort may abate with activity early in the tendinopathy but later progresses to the point of discomfort during exercise and at rest. With the knee flexed at 30 degrees, which relaxes the quadriceps, tenderness may be localized to the deep surface of the proximal attachment of the patellar tendon at the inferior pole of the patella. However, healthy active athletes sometimes have tenderness on examination as well.

The differential diagnosis includes patellofemoral syndrome, which arises from imbalances in the forces controlling tracking during knee flexion and extension. The patient usually complains of anterior knee pain, described as “behind” or “around” the patella, which is classically worse when ascending or descending stairs or on rising from a seated position. Occasionally, there is tenderness of the medial or lateral retinaculum or facets.

Imaging with ultrasonography and magnetic resonance imaging (MRI) may reflect collagen degeneration but is generally not specific to the distinctive history and physical examination findings. It is noted that some asymptomatic jumping athletes have similar appearances to those affected, and that prognosis and outcome are not predicted by such imaging.

**Ankle**

**Achilles Tendinopathy.** Achilles tendinopathy is a common overuse syndrome that typically affects male athletes. The Achilles tendon, named for the mythological Achilles, whose heel was not immersed in the River Styx as his mother dipped him in the river for its protective powers, arises from the medial and lateral heads of the gastrocnemius muscle and the deep layers of the soleus muscle and inserts on the calcaneal tuberosity. A major function is plantar flexion of the foot. It is the strongest muscle-tendon unit and areas of swelling and erythema should be evaluated. Acutely in Achilles tendinopathy, the tendon may be diffusely swollen and exhibit tenderness on palpation, usually greatest in the middle third. Typically, in the patient who has acute symptoms of tendinopathy, the area of swelling and tenderness does not move with dorsiflexion of the ankle joint.

On palpation, local heat, crepitation, and palpable tendon nodules or defects should be noted. Examination for ankle instability and biomechanical faults may be considered as well.

**Achilles Tendon Rupture.** Although rupture of the Achilles tendon most often occurs when preceded by tendon damage, it is possible for untrained athletes to apply excessive force and rupture the tendon, even in the absence of prior changes of tendinopathy. Partial and complete rupture may occur, most commonly in 30- to 40-year-old men. Complete rupture is more common in the middle-aged recreational athlete. Historically, the patient may note a “popping” sensation followed by acute weakness and inability to continue the exercise or sport. The patient may report that it felt as though someone kicked him or her in the back of the ankle or, if playing a racket sport, as if he or she were struck on the calf by a ball.

On physical examination, a defect in the tendon can sometimes be palpated. If enough time has elapsed to allow hematoma formation, bogginess may be noted over the injured area of the tendon. It is important to note that the ability to plantar-flex the foot is not incompatible with a complete rupture of the Achilles tendon. There are multiple plantar flexors of the foot and toes. Muscles such as the tibialis posterior, flexor digitorum longus, flexor hallucis longus, peroneus brevis, and peroneus longus can remain functional and therefore disguise a complete rupture with the ability to plantar-flex the foot.

The Simmonds (Thompson) test can be performed to evaluate for complete rupture. With the patient prone and feet hanging over the edge of the bed, the examiner squeezes the calf muscles at their widest point and looks for passive plantar flexion. The absence of plantar flexion is considered a positive finding, indicative of a complete tear of the Achilles tendon. The presence of plantar flexion does not, however, negate the possibility of a partial tear of the Achilles tendon.

**Diagnostic Strategies**

The diagnosis of tendinopathy is generally made on clinical grounds. Although plain radiographs may be helpful in
excluding bony abnormalities, ultrasonography has been recommended by some practitioners as the modality of choice for evaluating pathologic tendon conditions.\textsuperscript{42} Ultrasonography can be especially useful when other conditions (e.g., gouty arthritis) obscure the findings of concomitant tendinopathy. Although ultrasound imaging is employed in the emergency department, the use of this imaging technique for soft tissue evaluation in this setting is relatively unstudied and, thus, it is not frequently used.\textsuperscript{43,44} In cases of acute or chronic tendinopathy, one or more of the following features can be seen: loss of the fibrillar echotexture, focal tendon thickening, diffuse thickening, focal hypoechoic areas, extended hypoechoicogenicity, irregular and ill-defined borders, microruptures, and peritendinous inflammatory edema.\textsuperscript{45} Hypoechoic areas surrounding tendons provide evidence for surrounding soft tissue inflammation. In addition to tendinopathy, tendon tears, both partial and complete, can be delineated by ultrasonography.\textsuperscript{45} Magnetic resonance imaging has been used to visualize pathologic conditions of the tendon. It is able to provide high intrinsic tissue contrast, which permits the distinction between normal tendons and abnormal tendons, as well as providing the high spatial resolution that permits detailed anatomic structures to be identified. The resolution of the tendon by MRI can aid in the diagnosis of Achilles tendon disorders, which include rupture (complete or partial), postoperative assessment of tendinous healing, tendinopathy, tenosynovitis, and various tumors of the Achilles tendon.\textsuperscript{46}

\textbf{Differential Diagnosis}

The differential diagnosis for tendinopathy includes tendon ruptures, bursitis, ligamentous injuries, septic and inflammatory arthritis, nerve entrapment syndromes, and bony abnormalities such as fracture, foreign body, tumor, and osteomyelitis.

\textbf{Management}

The management of tendinopathy focuses on identification of the cause of discomfort; elimination of sources of primary tendinopathy; institution of treatment modalities such as analgesic medication, protection, relative rest, application of ice, compression, and elevation as necessary; modification of behavior to minimize or eliminate sources of continuing irritation; and, importantly, referral for appropriate follow-up care.\textsuperscript{47}

Cryotherapy (cold treatments, 20 minutes at a time every several hours, for the first 24 to 48 hours) may be beneficial. Nonsteroidal anti-inflammatory drugs (NSAIDs) are also sometimes indicated to provide pain relief, although there is little evidence to support a beneficial effect with their use because tendinopathies tend to represent a degenerative, rather than inflammatory, process.\textsuperscript{47} Graduated range-of-motion exercises may be useful after the period of immobilization. Although often used, the role of corticosteroid injection for most tendinopathies is unclear.\textsuperscript{48,49} The use of corticosteroid injection in the emergency department is controversial. Steroids should not be injected into such major tendons as the Achilles tendon and patellar tendon, which may be at risk for spontaneous rupture if already weakened.

\textit{Impingement Syndrome and Rotator Cuff Tendinopathies.} The treatment for rotator cuff tendinopathies and the impingement syndrome follows the treatment of tendinopathy in general. Emphasis is placed on physical rehabilitation and strengthening exercises. A significant proportion of patients will improve with conservative management. In those who do not, surgical intervention, such as acromioplasty or repair, may be indicated.\textsuperscript{\textsuperscript{50,51}}

\textbf{Calcific Tendinopathy.} The treatment of calcific tendinopathy is mainly conservative and consists of analgesia and brief sling immobilization because prolonged immobilization may result in adhesive capsulitis.\textsuperscript{17} The use of corticosteroids is controversial. Ultrasonography and extracorporeal shock wave therapy have been utilized with some success.\textsuperscript{26} A small percentage of patients who do not respond to the previously discussed interventions may need surgery. Localized disruption in the resorptive phase by needle lavage under fluoroscopy or in the operating room has been noted to be an efficacious therapy.\textsuperscript{26} Follow-up care is important because calcific tendinopathy has been described as the best known cause of reactive cuff failure.\textsuperscript{17}

\textbf{Lateral and Medial Epicondylitis.} In up to 95% of patients, epicondylitis will improve with conservative therapy.\textsuperscript{27} Initial efforts include making the patient more comfortable with the standard principles of protection, relative rest, cryotherapy, compression, elevation, medication (NSAIDs), and modalities of physical therapy. The term \textit{relative rest} implies the avoidance of abuse and not the absence of activity. Activities that aggravate the pain should be eliminated, and an attempt to protect the tendon through such strategies as a reduction in playing time or intensity should be considered. Control of force loads by bracing, improved performance technique, and use of appropriate equipment should also be considered. Follow-up evaluation should be ensured.\textsuperscript{28}

\textbf{De Quervain’s Tenosynovitis.} The initial treatment of de Quervain’s tenosynovitis consists of immobilization with a thumb spica splint, anti-inflammatory medications, and prompt, appropriate referral. Corticosteroid injection has been shown to be an effective treatment for de Quervain’s disease, and failure to respond may be due to anatomic variation or poor technique. Surgical decompression of the first dorsal compartment may be indicated if these treatments fail.\textsuperscript{33}

\textbf{Achilles Tendinopathy and Rupture.} In addition to routine conservative treatment, patients with Achilles tendinopathy should be referred for orthopedic evaluation and correction of limb malalignment with the use of orthotics or heel lifts. Eccentric loading exercise and low-energy shock wave therapy have been shown to be effective therapies for Achilles tendinopathy.\textsuperscript{52-54}

The management of Achilles tendon rupture may be either operative or nonoperative, depending on the patient involved. Appropriate consultation with an orthopedist is essential. A conservative approach, including immobilization in a short or long leg cast in the equinus position, may be indicated.\textsuperscript{55} Some authors note that complete ruptures in active athletes should be treated surgically in most cases.\textsuperscript{56} Although other risks and benefits must be taken into consideration, some studies indicate that early surgery may be indicated because the risk for Achilles tendon re-rupture is less.\textsuperscript{55,56}

\textbf{Disposition}

Most patients with tendinopathy are safely discharged home with proper discharge instructions, relative rest of the tendon, analgesia, and appropriate follow-up. The exception is elderly or disabled patients for whom the tendinopathy renders them unable to perform the activities of daily living. Although appropriate rest and analgesia provide symptomatic relief, underlying causes should be sought and modified.

\textbf{Bursitis}

\textbf{Perspective}

Bursae are closed, round, flat sacs lined by synovium.\textsuperscript{57,58} They occur at areas of friction between skin and underlying...
ligaments and bone. The bursa permits the lubricated movement of soft tissues over areas of potential impingement (e.g., subacromial bursa) and friction (e.g., olecranon bursa and prepatellar bursa). Many bursae are nameless, and new bursae can form as a result of frequent irritation. The two most common identifiable inflamed bursae are the olecranon and the prepatellar. When these bursae are inflamed, they are generally recognizable over the extensor surface of the elbow or the knee, respectively.

**Principles of Disease**

Many cases of bursitis are idiopathic in nature, but common identifiable causes of inflammation include infection (most often due to *Staphylococcus aureus*), trauma (which may predispose to infection), rheumatologic disorders (e.g., gout, pseudogout, anklyosing spondylitis, and rheumatoid and psoriatic arthritis), and other systemic diseases.

**Clinical Features**

**Olecranon and Prepatellar Bursitis**

Less than half of patients who present to the emergency department with olecranon or prepatellar bursitis show signs of an infectious origin. Distinguishing septic from nonseptic bursitis is not always straightforward, either on clinical grounds or as a result of diagnostic testing. Patients with septic bursitis generally present earlier in the clinical course and have more pain, tenderness, erythema, and warmth compared with those who have an inflammatory process. The most important predisposing factor in septic bursitis is trauma, which precedes septic bursitis in up to 70% of cases. Other predisposing factors for septic bursitis include chronic illness such as diabetes mellitus or alcohol abuse, chronic skin conditions such as atopic dermatitis, and previous noninfectious inflammation of the bursae such as rheumatoid arthritis or gout. It may also be seen more commonly in people in occupations in which repetitive knee (e.g., carpet layer) or elbow (e.g., miner) trauma is common.

The olecranon bursa, on the extensor surface of the elbow, is the only bursa of the elbow joint and is easily traumatized, resulting in inflammation, pain, and swelling. Septic bursitis involves the olecranon more commonly than the prepatellar bursa. Infection can occur from local trauma (e.g., puncture wound and laceration) but may also be present in the absence of visible trauma. Hematogenous bacterial seeding has been described as rare, probably due to the limited vascular supply of the bursal tissue; however, some series have noted up to an 8% incidence of an associated bacteremia. On physical examination, localized swelling and fluctuance are usually present. In the septic bursa, tenderness is present in more than 90% of patients, and there is evidence of a traumatic wound (e.g., abrasion and laceration) in half of patients. A noninflamed bursal effusion is usually present in nonseptic (e.g., traumatic and idiopathic) types of bursitis, although up to 45% of patients have mild tenderness, and one fourth have mild peribursal edema, warmth, and erythema. Fever is more commonly seen in patients with septic than in those with nonseptic bursitis. Most patients with septic bursitis present with swelling and peribursal cellulitis, and there may be peribursal soft tissue inflammation. Crystal-induced bursitis may reflect an acute inflammatory process, and the concomitant existence of septic bursitis in a patient with gouty bursitis has been described.

Passive range of motion should not produce much pain, with the exception of full flexion, at which point there may be discomfort as the inflamed bursa is compressed. Evidence of significantly diminished range of motion, generalized joint swelling, or other signs and symptoms of joint involvement (e.g., joint pain, warmth, and joint effusion) should raise a concern for septic arthritis. Although the olecranon and prepatellar bursae generally do not communicate with the joint space, one must consider this possibility in the differential diagnosis, especially if trauma is involved and the integrity of the underlying joint is disrupted. Arthrocentesis (to rule out septic arthritis) may then be indicated.

**Diagnostic Strategies**

When signs of acute inflammation are present, aspiration of the bursa is indicated to exclude the presence of infection or crystal-induced disease. Although a discussion of the technique of bursal aspiration is beyond the scope of this chapter, it should be performed observing sterile technique. A lateral approach utilizing an 18- to 20-gauge needle has been recommended. Other authors have described a distal approach when aspirating the olecranon bursa. Reports of sinus drainage from the center of the bursa have been described, but the relation to aspiration is unclear. In a prospective study of 47 patients with bursitis who underwent aspiration, only 3 developed a draining sinus, all around the center of the bursa and not at the site of aspiration. In this study, aspiration was performed at the distal aspect in olecranon bursitis and from the lateral aspect in prepatellar bursitis, but the three cases of sinus drainage occurred only in patients with olecranon bursitis. In cases of septic bursitis, the aspirate usually appears purulent but can occasionally appear serosanguineous or straw-colored. In the case of nonseptic bursitis, the aspirate may vary from bloody aspirate to straw-colored. The aspirate of an inflamed bursa should be sent for evaluation of white blood cell (WBC) count with differential, microscopy for crystals (if crystalline disease is suspected), Gram’s stain, and appropriate cultures and sensitivities. Some practitioners have suggested the use of a glucose level in the aspirate as an indicator of bacterial infection, but this has been shown to be neither very sensitive nor specific.

Organisms found on either Gram’s stain or culture are diagnostic for septic bursitis. If organisms are not seen on Gram’s stain, the WBC count may give an indication as to whether the cause is infectious. The noninfected bursa usually has a WBC count of less than 1500/µL (predominantly mononuclear cells) and uncommonly greater than 10,000/µL. The septic bursa has been reported to have WBC counts that range from fewer than 1000/µL to 300,000/µL (predominantly polymorphonuclear cells). A bursal fluid WBC count greater than 5000/µL suggests bursal fluid infection, even in the presence of a negative Gram’s stain. *Staphylococcus aureus* is the most common organism in bursal infection.

Since most cases of septic bursitis occur in the olecranon or prepatellar bursae, the diagnosis is made clinically in conjunction with aspiration. MRI can be used to aid in the diagnosis of inflammation or infection of deep bursae. Ultrasound has also been used as a modality for aspiration of deep bursae.

**Differential Diagnosis**

Conditions that mimic bursitis include underlying fracture and osteomyelitis. Radiographs and bone scan or MRI may be necessary to exclude these conditions. Other causes of the nontraumatic, nonseptic bursitis include rheumatoid arthritis, gout, pseudogout, scleroderma, anklyosing spondylitis, systemic lupus erythematosus, hypertrophic pulmonary...
osteoarthritis, Whipple’s disease, oxalosis, and idiopathic hypereosinophilic syndrome.\textsuperscript{57}

**Management**

The optimal treatment for septic bursitis is uncertain because large-scale clinical prospective trials in this area are lacking. Debate remains regarding the use of outpatient (oral) versus inpatient (intravenous) administration of antibiotics, duration of therapy, use of needle aspiration and incision and drainage, and use of operative intervention.\textsuperscript{56}

Patients who have bursal inflammation with suspicion (clinical or laboratory) of infection should be treated with appropriate antibiotics. Empirical therapy (including coverage for \textit{S. aureus} and \textit{Streptococcus} species) may be indicated until definitive culture results are available.\textsuperscript{58} Oral antibiotic therapy (some recommend 14 days) and treatment on an outpatient basis in the patient with uncomplicated bursitis and no underlying disease has been recommended as initial therapy.\textsuperscript{59} It must be kept in mind, however, that high failure rates (32–67\%) for outpatient treatment of septic bursitis have been described.\textsuperscript{60} One of the largest observational studies on the successful outpatient treatment of septic bursitis showed an admission rate of only 1 of 118 patients, but all patients in this study received sequential intravenous antibiotics at an outpatient clinic followed by oral antibiotic therapy. The median number of total days of intravenous therapy was four.\textsuperscript{67} Treatment in an observation unit or inpatient setting with intravenous antibiotics therefore should be considered for patients with significant symptoms, significant overlying cellulitis, or for patients unlikely to receive close follow-up.

Needle aspiration is a commonly used technique for the management of septic bursae. Stell showed a high success rate in the treatment of septic bursitis in patients receiving outpatient oral antibiotics following initial needle aspiration.\textsuperscript{60} Laupland and Davies showed no difference between patients who received aspiration (51\% of total patients) and those who did not, but the authors conceded that patients who had more severe disease were likely selected for drainage.\textsuperscript{67} Also, the diagnosis of septic bursitis was confirmed by culture in only 26\% of these patients, potentially underestimating the importance of bursal drainage in patients with true septic bursitis.\textsuperscript{68} Because needle aspiration is used for the diagnosis of septic bursitis, initial drainage at the same time seems warranted. Those with a purulent aspirate may require repeat aspiration at 1- to 3-day intervals if the effusion persists.\textsuperscript{69} In all cases, appropriate follow-up to assess response to therapy should be arranged. Warm soaks and wound care are also indicated. Surgical incision and drainage or bursectomy may also be necessary in severe, recurrent, or refractory cases.\textsuperscript{66}

The optimal treatment of nonseptic bursitis has not been clarified. Most cases improve with conservative therapy, although complete recovery can take many months.\textsuperscript{70} Similar times to recovery have been described for both septic and nonseptic bursitis.\textsuperscript{69} Aspiration can be considered in the initial treatment of acute nonseptic bursitis. Further conservative therapy includes the administration of NSAIDs and application of a compression dressing with an elastic bandage to prevent recurrent swelling. Systemic causes of bursitis (e.g., crystalline disease) should be treated appropriately. Avoiding local trauma is important to treat and successfully prevent bursitis.\textsuperscript{71} Recurrent olecranon bursitis may be caused by an underlying bone spur that needs resection.\textsuperscript{59} Steroid injection into a nonseptic bursa has been utilized as a treatment modality, but significant complications have been noted, such as skin atrophy over the bursa (20\%), chronic pain (30\%), and the development of septic bursitis (10\%).\textsuperscript{68} Other complications of intrabursal injection include bleeding, postinjection flare as a result of release of microcrystals, and tendon rupture.\textsuperscript{25} It should be noted that the bursal sac, with recent injection of a long-acting steroid, may reveal evidence of birefringent crystals under microscopy.\textsuperscript{57}

**Disposition**

Patients without underlying medical problems who present with uncomplicated septic bursitis can usually be discharged on appropriate oral antibiotics. Those with underlying diseases (e.g., immunocompromise, leukopenia, and diabetes) and those with systemic toxicity or severe bursal infection (e.g., purulent drainage) should be considered for intravenous antibiotics and inpatient therapy. Patients with a purulent aspirate may need repeat aspiration. Close follow-up is necessary to ensure response to therapy. Patients with presumed nonseptic bursitis should have close follow-up as well.\textsuperscript{59}

**Other Types of Bursitis**

**Subacromial Bursitis**

The subacromial bursa lies between the supraspinatus tendon and the acromion. Subacromial bursitis is thought to be nearly synonymous with supraspinatus tendinopathy and may be involved in the stages of rotator cuff impingement. Pain and tenderness, localized to the lateral aspect of the shoulder, and signs of impingement may be noted on physical examination.\textsuperscript{17} Although uncommon, there have been reports of septic subacromial bursitis.\textsuperscript{65,69}

**Trochanteric Bursitis**

The trochanteric bursa has both deep and superficial components. The deep bursa is located between the greater trochanter and the tensor fascia lata; the superficial bursa is located between the greater trochanter and the skin. Generally, middle-aged or older women report acute or chronic pain over the bursal area as well as the lateral thigh. Lying on the hip and walking may exacerbate the pain. Trochanteric bursitis can occur as a complication of rheumatoid arthritis. On examination, the pain of superficial bursitis may be reproduced by hip adduction and the pain of deep trochanteric bursitis reproduced with hip abduction. The hip joint should have normal examination findings.\textsuperscript{72} There has been a report of a trochanteric bursitis associated with bacterial endocarditis.\textsuperscript{69}

**Ischiogluteal Bursitis**

The ischiogluteal bursa is located adjacent to the ischial tuberosity and overlies the sciatic and posterior femoral cutaneous nerves. Inflammation, known as \textit{weaver’s bottom}, is described as pain over the center of the buttocks with radiation down the back of the leg. Sitting on a hard surface exacerbates the pain, and palpation over the ischial tuberosity causes discomfort.\textsuperscript{73}

**iliopsoas Bursitis**

The iliopsoas bursa is the largest bursa around the hip. It lies between the iliopsoas tendon and the lesser trochanter. The pain of iliopsoas bursitis usually presents as anterior hip pain that can radiate down the medial thigh to the knee and is increased on hip extension.\textsuperscript{25,72}
Anserine Bursitis

The anserine bursa lies deep to the three tendons (sartorius, gracilis, and semitendinosus) that form the pes anserina (“foot of the goose”) and superficial to the medial collateral ligament. The patient with anserine bursitis usually complains of medial knee pain approximately 2 or 3 cm distal to the joint line. There is usually tenderness to palpation in this area and occasionally swelling. Diabetes mellitus and possibly obesity and osteoarthritis of the knee are risk factors for development of this condition.

■ SYSTEMIC LUPUS ERYTHEMATOSUS

Perspective

Systemic lupus erythematosus (SLE) is a multisystem autoimmune connective tissue disorder with a broad range of clinical presentations, including renal failure and neurologic compromise. Symptoms and clinical courses vary widely, but patients with a known diagnosis of SLE are at risk for many different complications. Use of corticosteroids and immunosuppressive agents for therapy may cause further complications.

Background

The disease was originally described by Biett in 1822. The term *lupus erythematosus* was used by Cazanave to describe the cutaneous manifestations in 1851. Sir William Osler coined the term *systemic lupus erythematosus* in 1904 to describe many of the visceral manifestations. The term *lupus*, which means “wolf” in Latin, was used to describe the skin lesion, differentiating it from lupus vulgaris. It was not until 1949 that the lupus erythematosus cell was identified, allowing Haserick to describe the autoimmune nature of the disease.

Epidemiology

The incidence of SLE varies significantly among ethnic groups and populations, with an annual incidence in adults ranging from 1.9 to 5.6 per 100,000. The highest incidence, for women in their childbearing years, is 1 per 1000 in white women and 1 per 250 in black women. Seven women present with the disease for every man, with an 11:1 ratio during the childbearing years. Pediatric data suggest the incidence of SLE with onset before age 19 years is probably between 6 and 18.9 cases per 100,000 in white females and higher in black females (20–30 per 100,000). The incidence of SLE may have tripled since the 1970s. Factors thought to increase the prevalence include familial cases and a lupus-like syndrome caused by certain medications, including hydralazine, isoniazid, minocycline, procainamide, and quinidine.

Principles of Disease

The underlying mechanism is an autoimmune response with production of autoantibodies and a failure of the body to suppress them. There is a polyclonal activation of B cells with exaggerated production of autoantibodies. The abnormal cellular and humoral response to the formation of these autoantibodies is modified by genetic, environmental, and hormonal factors. Genetic factors include familial association and relationship to certain human leukocyte antigen (HLA) genotypes. Environmental factors play a role not only in the onset of SLE but also in triggering the “flares” (relapses). The most recognized environmental trigger is ultraviolet light exposure. Autoantibodies are also found in laboratory workers who handle SLE sera. An antecedent viral-like illness may occur at the outset of lupus or immediately before a flare. Exposure to certain drugs can also produce an SLE-like syndrome. Because 90% of patients with lupus are female, an important role for female hormones seems likely, although a protective role of male hormones is also possible. There may also be a link to Klinefelter’s syndrome. The different manifestations in different patients may reflect the varied autoantibodies produced, the varied organs targeted, and the individual patients’ responses to the autoantibodies. These autoantibodies may induce immune complex formation or interact directly at the site, binding to tissue, resulting in different disease manifestations. Pathologic findings are manifestations of the inflammation, inflammatory vasculitis, noninflammatory blood vessel damage, and immune complex deposition.

Clinical Features

The triad of fever, joint pain, and rash in a woman of childbearing age should suggest the diagnosis of SLE. However, the disease ranges from mild illness with cutaneous abnormalities to severe life-threatening complications such as renal failure and lupus cerebritis.

The American Rheumatism Association Revised Criteria for the Classification of Lupus were published in 1982 and updated in 1997. These criteria consist of 11 conditions that are associated with SLE. Patients must have four criteria present, serially or simultaneously, to be given the diagnosis of SLE (Box 116-1).

Rheumatologic

The vast majority of patients with SLE will experience arthritis. Polyarthralgias and myalgias occur at some time during the course of the disease in 90% of patients. As in rheumatoid arthritis, the inflammation of the hands, specifically the proximal interphalangeal and the metacarpophalangeal joints, is symmetrical and nonerosive. Although the initial presentation can mimic that of rheumatoid arthritis, joint deformities are less common. Thirty percent of patients develop hitchhiker’s...
Ulcerations and are present in up to 19% of patients. Vascular lesions can be seen with small, shallow ulcers, and discoid lupus. Only 10% of patients may be the first sign of SLE or may accompany flares of the disease. It is a maculopapular rash over the cheeks extending to ultraviolet light. Discoid lupus consists of an erythematous raised plaque with scales usually on the face, head, or neck. This can be associated with alopecia. Only 10% of patients with discoid lupus have SLE, whereas up to 25% of patients with SLE develop skin lesions consistent with discoid lupus. Mucous membrane lesions can be seen with small, shallow ulcerations and are present in up to 19% of patients. Vascular lesions such as ulcerations, purpura, and digital infarcts may occur.

Renal

Clinical nephritis, defined as persistent proteinuria, is seen in approximately 50% of patients, although mesangial and glomerular immunoglobulin deposition is seen in almost all patients with SLE. Most patients have no symptoms from their lupus nephritis until it progresses to nephrotic syndrome or frank renal failure. Serum creatinine is an insensitive indicator of early renal disease because many nephrons must be involved before any elevation is seen. In patients with renal disease, the urinalysis shows hematuria, proteinuria, and red blood cell casts. Active urine sediment with excretion of red blood cell casts and increasing proteinuria is worrisome.

These patients may benefit from aggressive therapy with steroids or other immunosuppressive therapy. With aggressive treatment, survival has increased to 95% at 5 years and 75 to 80% at 10 years in Western Europe and the United States. Indications for treatment include worsening renal failure, decreasing serum complement levels, increasing antinuclear antibody, false-positive serologic test for syphilis, and confirmed by treponema pallidum fluorescent treponemal antibody absorption test. Antiphospholipid antibody, based on abnormal serum level of IgG or IgM anticardiolipin antibody. Positive test result for lupus anticoagulant.

Classification based on 11 criteria. Patient is diagnosed with SLE if any four or more criteria are present, serially or simultaneously, during any interval of observation. Modified from Hochberg M: Updating the American College of Rheumatology revised criteria for classification of systemic lupus erythematosus. Arthritis Rheum 40:1725, 1997.

**Dermatologic**

The malar or butterfly rash is the hallmark of SLE (Fig. 116-1). This facial eruption, seen in up to 50% of patients with SLE, may be the first sign of SLE or may accompany flares of the disease. It is a maculopapular rash over the cheeks extending over the bridge of the nose. It can be exacerbated by exposure to ultraviolet light. Discoid lupus consists of an erythematous raised plaque with scales usually on the face, head, or neck. This can be associated with alopecia. Only 10% of patients with discoid lupus have SLE, whereas up to 25% of patients with SLE develop skin lesions consistent with discoid lupus. Mucous membrane lesions can be seen with small, shallow ulcerations and are present in up to 19% of patients. Vascular lesions such as ulcerations, purpura, and digital infarcts may occur.

**Figure 116-1.** The malar or butterfly rash is the hallmark of SLE. (From Habif TP: Clinical Dermatology, 4th ed. New York, Mosby, 2004, pp 592–606.)

**Neurologic**

Nervous system manifestations are varied and include seizures, stroke, psychosis, migraines, and peripheral neuropathies. These symptoms may appear early in the course of the disease but are rarely the initial sign of SLE. Central nervous system (CNS) involvement occurs in approximately 50% of patients with SLE. The most common form of neurologic
involvement is cognitive impairment, occurring in 80% of SLE patients 10 years after diagnosis. Seizures are also a common manifestation in up to 70% of patients with CNS involvement.\textsuperscript{20} Strokes are common as well, especially in association with antiphospholipid syndrome (APS). Frank psychosis can be seen, either as a manifestation of SLE or as a result of corticosteroid use. Lupus cerebritis should be considered in any patient with SLE who exhibits a change in behavior or mental status. The presence of infection should also be considered, especially in patients receiving immunosuppressive agents. These patients are at risk for bacterial, fungal, and tuberculous infections in addition to abscesses. Other causes include uremia and hypertensive encephalopathy. Mononeuritis multiplex and peripheral neuropathy have also been described.

A computed tomography (CT) scan is useful in patients with gross focal neurologic deficit to assess for bleeding or edema associated with an embolic stroke. A magnetic resonance imaging (MRI) scan is much more sensitive for small infarcts, edema, or evidence of vasculitis. Full recovery from neuropsychiatric manifestations is approximately 70 to 85%; however, the mortality from such events is 10 to 15%.\textsuperscript{19}

**Cardiac**

Pericarditis is the most common cardiac manifestation of SLE, reported in 30% of patients.\textsuperscript{21,22} The diagnosis may be determined on the basis of electrocardiographic (ECG) findings alone, or patients may have signs and symptoms of fever, tachycardia, chest pain, and transient cardiac rubs. Pericarditis is associated with effusion in 20% of patients; however, this rarely progresses to tamponade.\textsuperscript{23} Purulent pericarditis related to \textit{Staphylococcus aureus} and tuberculosis has been reported in patients taking steroids. Purulent pericarditis, which is exudative with a high protein and white blood cell count,\textsuperscript{24} may mimic the effusion seen with SLE, which causes a transudative, serous fluid. Pericarditis in SLE is generally benign and responds well to corticosteroids.

Myocarditis resembling cardiomyopathy is clinically diagnosed in fewer than 10% of patients with SLE but is found in 40% of patients at autopsy.\textsuperscript{25} Some degree of left ventricular dysfunction may be found in a large number of patients with SLE.\textsuperscript{26} It may be accompanied by congestive heart failure, ventricular dysrhythmia, tachycardia, or nonspecific ECG changes. Severe myocarditis should be treated with large doses of systemic corticosteroids, control of hypertension, and correction of volume overload.

A noninfectious endocarditis, as described by Libman and Sachs, produces vegetative growths on the valves that are usually clinically silent; however, these may be complicated by infection, valvular dysfunction, and, rarely, thromboembolism.\textsuperscript{27} Libman-Sachs vegetations are seen in up to 10% of patients with SLE.\textsuperscript{28} The mitral valve is most commonly involved, although all four valves may have vegetations. Valvular dysfunction may occur independent of vegetations secondary to valvulitis, mucoid degeneration, or aortic dissection. The aortic valve has the highest incidence of hemodynamically significant regurgitation, followed by the mitral valve.

Vasculitis of the coronary arteries or accelerated atherosclerosis related to corticosteroid use may cause coronary ischemia. Mortality from coronary artery disease (CAD) is seen in up to 30% of patients with SLE despite improved survival in renal and cerebral SLE.\textsuperscript{29} Coronary vasculitis, although rare, is best treated with steroids, whereas the atherosclerosis is best treated with conventional methods including aspirin, nitrates, beta-blockers, angioplasty, or bypass surgery. Treatment differences make the distinction between the two entities important. The diagnosis can be made by coronary angiography, with evidence of aneurysmal dilatation of the coronary arteries seen in patients with vasculitis.\textsuperscript{21} Patients with SLE, hypertension, smoking, and hypercholesterolemia are at significantly increased risk for CAD and should be treated aggressively for these problems as well as screened regularly for CAD.\textsuperscript{21,22}

Patients with SLE tend to have systemic hypertension secondary to lupus nephritis and steroid use, with all of the resultant complications of hypertension. The incidence has been reported as 25 to 50% of patients with SLE. Hypertension is noted in patients who take high, long-term doses of corticosteroids.

**Pulmonary**

Pleural effusions and pleurisy are common. Pleural effusions, seen in 12% of SLE patients, are usually exudative in nature. Pleural fluid glucose levels are usually similar to serum glucose levels, in contrast to those of rheumatoid arthritis, in which the pleural fluid glucose level is very low. Other manifestations include pulmonary infarcts and hemorrhage. Lupus pneumonitis causes diffuse interstitial infiltrates, although patients have usually had the disease for several years before they suffer from pneumonitis. Bacterial, fungal, and opportunistic infections must be considered, especially in patients taking immunosuppressive agents, before a diagnosis of lupus pneumonitis is given. Patients with SLE are particularly at risk for pneumococcal disease, in part because of autosplenectomy or splenic dysfunction. Patients with SLE may also develop chronic interstitial infiltrates leading to pulmonary fibrosis. These patients need inpatient treatment, and their conditions may progress to chronic hypoxia, pulmonary hypertension, and right-sided heart failure.\textsuperscript{27}

**Gastrointestinal**

Gastrointestinal complaints in SLE are common, ranging from oral ulcerations to the much more serious intestinal vasculitis. Oral ulcerations usually accompany disease flares. Esophageal dysmotility is occasionally seen, but it is much less common than in patients with scleroderma. Patients with intestinal pseudo-obstruction may have crampy abdominal pain and a clinical and radiographic picture consistent with obstruction. They should be observed for resolution. Pancreatitis can result from either an SLE flare or corticosteroid therapy. Spontaneous bacterial peritonitis is also described. Elevated liver function tests are common, usually the result of the medications given to treat SLE, such as azathioprine. However, infection with cytomegalovirus while taking immunosuppressive agents may also occur. Portal hypertension caused by scarring and fibrosis is seen in 4% of patients.\textsuperscript{27} The most serious complication is intestinal vasculitis, a syndrome of abdominal pain, bloody diarrhea, and evidence of vasculitis elsewhere. This vasculitis may progress to perforation or gangrene, resulting in peritonitis.

**Hematologic**

Hematologic and vasculitic problems are complex. A normochronic, normocytic anemia is found in approximately 50% of patients with SLE, with anemia of chronic disease being the most common form.\textsuperscript{29} Thrombocytopenia occurs in 25% of patients. Treatment for severe thrombocytopenia is controversial, with some authors advocating use of vinca alkaloids and intravenous gamma globulin.\textsuperscript{30} Splenectomy is controversial. Some believe that splenectomy exacerbates the disease. Thrombotic thrombocytopenic purpura and immune idioopathic thrombocytopenic purpura have also been reported.
in patients with SLE.\textsuperscript{30} Leukopenia is common with disease flares as well.

**Diagnostic Strategies**

The diagnosis of SLE can be difficult. The fundamental rule is that a patient must have 4 or more of the 11 criteria to qualify for the classification category of SLE. Rarely can the diagnosis of SLE be made with absolute certainty at the first onset of symptoms. As such, it has been common for rheumatologists to refer to cases as probable, definite, or classic.\textsuperscript{31} The diagnosis of SLE is often confirmed with antinuclear antibodies (ANAs). Positive ANAs occur in more than 95% of patients with SLE.\textsuperscript{32} The degree of positivity of the test is important, with higher titers having a positive predictive value. ANAs may also be positive in elders taking certain medications, such as hydralazine and procainamide, as well as with subacute bacterial endocarditis, infectious hepatitis, and other immune diseases such as primary biliary cirrhosis. Five percent to 7% of healthy people may also have a positive ANA.\textsuperscript{32} Antibodies to dsDNA and anti-Smith (anti-Sm) antibodies are most specific for SLE.\textsuperscript{33} Patients with disease flares may show an increase in their ANA or dsDNA titers. Decreases in complement levels for C3 and C4 also correlate with disease flares in certain patients. The erythrocyte sedimentation rate (ESR) is a very poor index of disease activity. Patients who have an ESR of 50 to 100 mm/hr often show minimal disease activity. C-reactive protein levels often remain low except in the presence of concurrent infection. Patients with SLE may have a false-positive Venereal Disease Research Laboratory or Rapid Plasma Reagin result, and this is also one of the diagnostic criteria.

**Management**

The treatment of SLE is controversial because the manifestations and severity vary widely among patients. After many years, new biotherapies are yielding improvements in the management of SLE. General treatments that continue to be recommended include avoidance of stress and fatigue, which can exacerbate symptoms. Approximately one third of patients are photosensitive and should avoid sunlight and use sunscreen. Not smoking is also recommended because smoking increases the already higher risk of accelerated atheroma and studies show that smoking increases the likelihood of developing or worsening lupus.\textsuperscript{34} Oral contraceptives may also exacerbate symptoms, and only low-estrogen oral contraceptives should be used. However, studies indicate that oral contraceptives and hormone replacement may be less hazardous than once thought.\textsuperscript{35}

Acetaminophen may be useful for mild to moderate pain control. Drug therapy starts with anti-inflammatory agents. Aspirin and nonsteroidal anti-inflammatory drugs (NSAIDs) have been used to treat minor inflammatory complaints such as arthralgias, pleurisy, and pericarditis. The maximum recommended doses of these agents are usually needed. These agents should be avoided in patients with severe gastrointestinal complications or thrombocytopenia. Patients with lupus nephritis should also avoid NSAIDs because the inhibitory effect on prostaglandins may reduce renal function, confusing the clinical picture of worsening renal failure. Some NSAIDs, including ibuprofen, have also been associated with aseptic meningitis, with headache, fever, and meningismus.\textsuperscript{36} Cerebrospinal fluid studies in these patients show lymphocytosis, elevated protein levels, and sterile culture.

Corticosteroids are usually the next agent of choice. Topical application controls most cutaneous manifestations. Oral corticosteroids are prescribed in dosages that control disease activity. Minor disease activity (e.g., arthralgias, fatigue, and pleurisy) is usually controlled with 0.5 mg/kg or less in a single daily dose. With minor symptoms, however, anti-inflammatory and antimalarial drugs such as hydroxychloroquine have been advocated to avoid the long-term complications of corticosteroids. Major disease activity (e.g., hemolytic anemia and severe thrombocytopenia) is usually controlled with prednisone 1.0 mg/kg/day. With lupus cerebritis and acute worsening of lupus nephritis, methylprednisolone 1.0 g intravenously (IV) once daily may be given for several days. Treatment of glomerulonephritis with long-term steroids has not been proved to alter the outcome or course in patients with SLE, and their long-term use remains controversial.\textsuperscript{30,37} When tapering, corticosteroids may be changed to an alternate-day dosing regimen; however, some patients may experience disease flares at these dosages.

Antimalarial drugs are also effective for the cutaneous and musculoskeletal manifestations of SLE. Hydroxychloroquine and chloroquine are given on an outpatient basis in a loading dose for 4 weeks, followed by maintenance dosing when these symptoms are under control. The underlying mechanism by which these medications work is unclear. Withdrawal of these medications may result in a disease flare. The antimalarial agents can result in two major ophthalmologic side effects. Corneal deposits, easily seen on slit-lamp examination in patients who complain of floaters in the visual field, are reversible with drug withdrawal or decreased dosage. The second complication, an irreversible retinopathy, is unrelated to the corneal deposits. All patients with SLE who take antimalarial medications should be observed biannually by an ophthalmologist to detect evidence of retinopathy that may lead to blindness. If evidence of retinopathy appears, patients should stop taking the antimalarial medication under a rheumatologist’s supervision.

Immunosuppressive agents (e.g., azathioprine, methotrexate, and cyclophosphamide) are reserved for patients with severe renal or cerebral disease in whom other therapies have failed or for patients who have not tolerated corticosteroids.\textsuperscript{37} Cyclophosphamide is now one of the standards for treating SLE, most notably with renal involvement, and studies support its effectiveness.\textsuperscript{35} Studies examining the use of immunosuppressants have shown decreased chronic renal scarring and reduced likelihood of end-stage renal disease without an increase in mortality.\textsuperscript{38} The toxicities of such drugs are numerous and include infections, myelosuppression, and future risk of neoplasms.\textsuperscript{37}

Newer treatments include autologous marrow stem cell transplantation, intravenous immunoglobulins, and mycophenolate mofetil, an inhibitor of purine synthesis.\textsuperscript{14,39} Rituximab and new anti-B-cell drugs hold promise for the treatment of severe SLE.\textsuperscript{35} All of the trials involving patients are small, of short duration, or anecdotal. A controlled clinical trial with significant power is needed to prove the efficacy of these therapies in patients with SLE.\textsuperscript{35,39}

**Special Considerations**

**Drug-Induced Lupus.** Drug-induced lupus was first described in 1954 by Dustan and colleagues and Perry and Schroeder.\textsuperscript{40,41} Procainamide was first implicated in 1962 by Ladd.\textsuperscript{42} Since then, a large number of agents have been implicated, with hydralazine, quinidine, and procainamide being the most common (Table 116-1). Patients with drug-induced lupus usually present with skin and joint manifestation; renal and neurologic features are very rare.\textsuperscript{3} The full manifestations are present in less than 1% of patients taking high-risk drugs,

*Removed from market because of lupus-like syndrome.

Although a positive ANA titer can be found in more than 50% of patients taking high-risk drugs. The patients are usually women, middle-aged or older, and rarely black, but these findings may be representative of the group of patients taking these drugs. The condition is usually reversible when the agents are stopped, with resolution within days or weeks; however, manifestations lasting for years have been reported. In patients with significant pleuropicardial disease, a short course of tapered steroids has been used successfully when the implicated medication has been discontinued.

Antiphospholipid Antibody Syndrome. Synonyms for the antiphospholipid antibody syndrome (APS) are anticardiolipin antibody, lupus anticoagulant, and Hughes' syndrome. Diagnosis requires that a patient have both a clinical event (thrombosis or pregnancy loss) and an antiphospholipid antibody (aPL) documented by a solid-phase serum assay (anticardiolipin), an inhibitor of phospholipid-dependent clotting (lupus anticoagulant), or both. The lupus anticoagulant and anticardiolipin antibody are antiphospholipid antibodies that bind to the prothrombin activator complex. This binding results in a prolongation of the partial thromboplastin time (PTT) but is clinically associated with clotting. Antiphospholipid antibodies are found in young healthy controls at a prevalence of 1 to 5% for both anticardiolipin antibodies and lupus anticoagulant antibodies. Among patients with SLE, the prevalence is much higher, ranging from 12 to 30% for anticardiolipin antibodies and 15 to 34% for lupus anticoagulant antibodies. This disorder can also be seen in patients with human immunodeficiency virus (HIV), in some malignancies, and with drug-induced lupus. Patients without evidence of SLE have a much lower incidence of complications. A prolonged PTT that is not corrected when the patient's sample is mixed 50:50 with normal serum suggests the presence of an inhibitor; the lupus anticoagulant and anticardiolipin antibody can then be found with further testing.

The spectrum of the clinical manifestations of APS is wide. Some patients may have repeated episodes of arterial or venous clotting, including recurrent strokes and pulmonary emboli. Elevated serum creatinine values may be a result of renal vein thrombosis, seen on CT with contrast, mimicking worsening nephritis. Multiple spontaneous abortions have been reported (Box 116-2).

This syndrome may also be associated with thrombocytopenia, with clinically significant bleeding, and with neuropsychiatric disorders believed to be secondary to cerebral ischemia and infarcts. Patients who have evidence of APS may still undergo surgery, with routine precautions for deep vein thrombosis. Despite the prolonged PTT, there is minimal risk for prolonged bleeding unless thrombocytopenia is also present. Any patient with APS and a documented thrombosis should receive anticoagulants, with a goal of maintaining an international normalized ratio (INR) of 2.5 to 3.0.

Pregnancy. Recurrent spontaneous abortions occur in some patients with APS. Subcutaneous loxostatin with low-dose aspirin throughout pregnancy is currently the treatment of choice. As the pregnancy progresses, there is a risk of worsening manifestations of SLE and nephritis. These patients are also at risk for pregnancy-induced hypertension. In patients who do not respond to subcutaneous loxostatin, monthly doses of intravenous gamma globulin may be effective, although this increases the risk of preeclampsia and preterm delivery. Patients with evidence of thrombosis and APS should receive anticoagulation and be admitted for further workup. Corticosteroids in combination with aspirin have shown some benefit in maintaining the pregnancy. Although they cross the placenta and show little evidence of fetal harm, corticosteroids are a second-line agent because of complications of long-term, high-dose therapy. Other medications, including NSAIDs, immunosuppressive agents, and antimalarials, should be stopped, although evidence shows that hydroxychloroquine is...
effective and safe in pregnancy. These patients should be referred to a high-risk obstetrician early in the pregnancy.

Neonatal lupus syndrome is usually diagnosed by dermatologic manifestations of lupus and is associated with transient anemia and thrombocytopenia. Neonates can also experience congenital complete heart block that may require permanent pacing. The congenital heart block has been associated with transmission of a maternal antibody to anti-SSA (Ro).

Complications of Therapy

The complications of SLE are many and varied because of the systemic nature of the illness. Treatment of the disease causes further complications. Treatment with NSAIDs can worsen lupus nephritis, either by causing interstitial nephritis or by inhibiting prostaglandins.

Corticosteroids are associated with well-known, long-term complications, including steroid-induced diabetes, osteoporosis and resultant fractures, weight gain, pancreatitis, osteonecrosis, accelerated atherosclerosis, and, most important, immunosuppression. Patients receiving steroid therapy should be monitored for evidence of infection and should be evaluated for any episode of fever. Patients taking corticosteroids should also be given stress-dose steroids with hydrocortisone 100 mg IV every 8 hours for any systemic infection, surgery, delivery, or obvious stressor.

Patients using antimalarial agents are at risk for dose-related corneal deposits, which can be managed by outpatient drug discontinuation and rheumatology follow-up. The retinopathy associated with antimalarial agents is irreversible and may progress to blindness. Prompt attention by an ophthalmologist is important.

Patients taking immunosuppressive agents are also at risk for infection, especially with gram-negative organisms, encapsulated gram-positive organisms, herpes zoster, and opportunistic organisms. Febrile patients who are receiving azathioprine, methotrexate, or cyclophosphamide should be admitted, whether a source is evident or not, because gram-negative or streptococcal sepsis occurs in this population. Patients with localized herpes zoster should be admitted for intravenous acyclovir administration to prevent viral dissemination.

Disposition

Because of the systemic and varied nature of the disease, there are no hard and fast rules about admission for complications of SLE. Patients without a previous diagnosis of lupus may be admitted for workup and treatment of possible connective tissue disease if they have symptoms that warrant immediate diagnosis (e.g., pericarditis, myocarditis, pleural effusion or infiltrates, evidence of vasculitis, or renal insufficiency). In the patient who has monoarticular or polyarticular arthritis, the joint can be aspirated in the emergency department if fluid is present. Further workup can be done on an outpatient basis by a primary care physician or rheumatologist. NSAIDs may alleviate the symptoms.

Patients with known SLE may come to the emergency department for a flare of their disease or for new systemic complaints, including fevers. Patients with known disease can usually tell if the symptoms are consistent with a previous flare or different. Patients with worsening disease who take large doses of steroids or immunosuppressive agents should be admitted for consideration of other diagnoses or more aggressive therapy. Patients with known disease and increasing arthritic pain, or mild flares without fever, may be effectively treated with an increase in their NSAID or corticosteroid dosages and prompt follow-up with their rheumatologists.

Patients with evidence of lupus nephritis and worsening renal failure should be admitted for aggressive therapy with steroids or immunosuppressive agents. The serum creatinine level may be elevated, but it is a poor indicator of disease. Urinalysis is more sensitive than serum creatinine for the diagnosis of nephritis. Proteinuria and red blood cell casts may indicate nephritis. Treatment for lupus nephritis should be done in conjunction with a rheumatologist or nephrologist. Consideration of renal vein thrombosis is also warranted in patients with evidence of APS or nephrotic syndrome.

Mental status changes in the patient with SLE should be evaluated thoroughly because lupus cerebritis is a diagnosis of exclusion. Infections, including meningitis, pneumonia and urinary tract infections, electrolyte imbalances, hypoxia or hypoglycemia, and medications all can cause altered mental status. A CT scan to assess for hemorrhage, especially in the hypertensive, thrombocytopenic, or anticoagulated patient, should be considered. Lumbar puncture to evaluate for infection may be indicated if the patient is febrile or immunocompromised. MRI may reveal abnormalities with increased signal intensity in the area of involvement. Cerebral ischemia may cause acute mental status changes as a result of a lupus vasculitis or thrombosis associated with APS. Consultation with a neurologist is prudent before giving high-dose steroids for lupus cerebritis. Patients with seizures should be treated in the routine manner, with ongoing care supported by a neurologist.

Patients with cardiac or pulmonary complaints should be admitted for observation or therapy. Those who take corticosteroids are at high risk for coronary artery disease. Patients with chest pain should be aggressively evaluated for myocardial infarction. If pericarditis is suspected, evaluation of pericardial effusion may be necessary, although tamponade is rare. Patients with myocarditis should be observed for evidence of congestive heart failure and dysrhythmias. Patients taking immunosuppressive agents should be given antibiotic prophylaxis for invasive dental and genitourinary procedures.

Pulmonary complaints may indicate either common or atypical disease. Patients with fever and infiltrates may have community-acquired pneumonia, especially pneumococcal disease, but opportunistic infection, atypical tuberculosis, and lupus pneumonitis need to be considered. Sputum culture and pulmonary consultation may be appropriate, especially in the hypoxic patient. Hypoxic patients may have pulmonary embolism as a complication of antiphospholipid antibody with thrombosis. Patients with pleural effusions should be admitted for diagnostic thoracentesis and treatment. Pleural effusions may be complicated by infection, tuberculosis, or malignancy.

Patients with abdominal pain are typically young women of childbearing age. Workup should therefore include a pelvic examination and pregnancy test. Laboratory examination may not be helpful without baseline values because many patients are chronically anemic and the white blood cell count may be elevated in those taking corticosteroids. Evidence of an increased anion gap or metabolic acidosis may be indicative of lactic acidosis. Abdominal films may be helpful to show bowel wall thickening or free air. Consultation with a surgeon, overnight observation for serial examinations, or a CT scan may be necessary to diagnose vasculitic problems, abscess in immunocompromised patients, or routine causes of abdominal pain. Even if the patient has a common cause of abdominal pain (e.g., pelvic inflammatory disease, pancreatitis, peptic ulcer disease, or biliary colic), admission may be necessary for administration of stress-dose steroids and workup of fever.

SLE predisposes patients to anemia and thrombocytopenia. Patients should be admitted if there is evidence of active hemolysis with decreased hematocrit or if hemolysis is evident.
on the blood smear. Patients with thrombocytopenia should be admitted if there is evidence of bleeding or if platelet counts are severely decreased (<50,000/mm³). If the patient is actively bleeding, platelet transfusion is appropriate; however, rapid destruction of the platelets may occur. Simultaneous administration of intravenous corticosteroids and intravenous gamma globulin aids in increasing the platelet count and decreasing the amount of platelet destruction.

Patients with evidence of arterial or venous thrombosis should be admitted for anticoagulation and possible embolotomy. Anticoagulation can be achieved acutely with heparin, although large doses are occasionally needed to overcome the antibody effect. The PTT, if not elevated, can be followed to assess for evidence of adequate anticoagulation, with careful observation for bleeding in patients who are also thrombocytopenic. Otherwise, patients with prolonged PTT and evidence of the lupus anticoagulant can be monitored with thrombin times if necessary. Patients with an INR less than 2.5 should still be considered to have a possible thrombus if they have a history of APS.

Pregnant patients with SLE should have early follow-up with a high-risk obstetrician. Emergency delivery for the pregnant patient with SLE should include stress-dose steroid administration and close observation of the neonate for congenital complete heart block. Emergent cardiac pacing may be necessary.

Patients experiencing overwhelming sepsis or shock should be given stress-dose steroids in the emergency department with hydrocortisone 100 mg IV. Broad-spectrum antibiotics may also be given empirically after appropriate cultures are obtained. Adrenal insufficiency from abrupt discontinuation of steroids is another possible cause of shock. If the patient is unstable, admission to the intensive care unit is warranted.

#### THE VASCULITIDES

**Perspective**

The vasculitic syndromes are a heterogeneous group of disorders of unknown etiology characterized by inflammation and necrosis of different-sized blood vessels. Depending on the size, distribution, and severity of inflammation in the affected vessels, vasculitis can result in clinical syndromes that vary in severity from a minor self-limited rash to a life-threatening multisystem disorder.

**Background**

The first classical description of a vasculitic syndrome was in 1866 by Kussmaul and Maier. This syndrome is now known as *polyarteritis nodosa*. By the 1950s, many investigators realized that there were a number of distinct forms of vasculitis. In 1952, Zeek presented the first classification system. Since then, a number of well-described disease states have been attributed to vasculitic syndromes. Because the etiologies of most forms of vasculitis remain unknown, the most commonly used method for classifying the vasculitides is the size of the predominant blood vessels involved (Box 116-3). Current classification schemes recognize approximately 20 primary forms of vasculitis, as well as several categories of secondary vasculitis (e.g., other rheumatologic diseases, malignancies, and infection).

**Epidemiology**

In general, the vasculitides are relatively uncommon, although not rare, in Western countries. Approximately 1 of 2000 adults has some form of vasculitis, and each year vasculitis develops in approximately 1 of 7000 adults. In the United States, the most common forms of primary systemic vasculitis are giant cell arteritis, Wegener's granulomatosis, and microscopic polyangiitis.

**Principles of Disease**

Vasculitic syndromes are thought to arise because immune complexes are deposited in vessel walls and the complement system is activated. The complement system then stimulates accumulation of polymorphonuclear cells at the site and release of lysosomal enzymes, resulting in vessel wall damage and

HIV, human immunodeficiency virus; SLE, systemic lupus erythematosus.
Temporal Arteritis

Temporal or giant cell arteritis, the most common vasculitis, is a chronic disease affecting predominantly large to medium vessels. It is characterized by granulomatous inflammation with multinucleated giant cells, and the distribution is most common in branches of the carotid artery but may involve any large or medium artery. The disease is most commonly seen in women in the sixth and seventh decades of life.

The onset of temporal arteritis tends to be gradual but can be abrupt, and systemic manifestations including fever, anorexia, and weight loss are present in up to half of patients. The classical symptoms are consistent with ischemia to the organs fed by branches of the internal and external carotid artery: visual loss in one eye, temporal artery tenderness, and jaw claudication. A headache is probably the most frequent initial symptom and occurs in two thirds of patients. Some patients experience central retinal occlusion or transient diplopia. Approximately 30 to 40% of patients also have myalgia, with patients complaining of severe myalgias and early morning stiffness of the muscles of the shoulder and pelvic girdle. On physical exam, the frontal or parietal branches of the superficial temporal arteries may be thickened or occasionally erythematous, and the pulses may be decreased or absent.

The diagnosis is relatively straightforward in the presence of the typical cranial manifestations. Helpful laboratory findings include elevated ESR (usually >100 mm/hr on a Westergren test), elevated C-reactive protein, and anemia. Although the role of ultrasonography and high-resolution magnetic resonance imaging in diagnosis is being studied, temporal artery biopsy remains the standard for diagnosis. Criteria for classification of temporal arteritis have been formulated by the American College of Rheumatology (Box 116-4).

Permanent partial or complete loss of vision in one or both eyes occurs in up to 20% of patients, so early diagnostic and therapeutic efforts are targeted to minimize this complication. Affected patients may report partially obscured vision, which may progress to total blindness. If untreated, the other eye is likely to become affected within 1 or 2 weeks. Amaurosis fugax is an important visual complaint that precedes permanent vision loss in 44% of patients.

Corticosteroids are the treatment of choice for temporal arteritis and the response is rapid. Treatment should be started for any patient with a high clinical suspicion of temporal arteritis. Steroids do not significantly change the results of the biopsy and may prevent progression to visual loss. Prednisone should be started at a dosage of 1 mg/kg/day until biopsy can be performed. Patients with severe disease or impending visual loss should be hospitalized and given high-dose steroids until the diagnosis is obtained. The likelihood of visual symptom resolution correlates with the time of corticosteroid initiation: More than 50% of patients treated in the first 24 hours can expect to recover compared to only 6% of patients treated after the first 24 hours. Although there is no consensus regarding treatment duration or tapering schedules, most patients are given the initial dose of steroids for 2 to 4 weeks and then a slow tapering of the steroid dosage over several weeks, although relapse rates are lower in those who use them longer (1 or 2 years).

Takayasu’s Arteritis

Takayasu’s arteritis (pulseless disease), named for the Japanese ophthalmologist who first described the ocular manifestations in 1908, is a chronic, recurrent, inflammatory vascular disease that primarily affects the aorta and its major branches. It is characterized by lymphocytic infiltration and fibrosis of the vessels, resulting in marked thickening of the intima and adventitia, eventually leading to obstruction of the arteries and ischemic complications. Adolescent girls and women in their second and third decades are predominantly affected, and women are affected eight times more frequently than men. The syndrome is most commonly seen in Japan, Southeast Asia, India, and Mexico. In the United States, the annual incidence is approximately 1 to 3 cases per 1 million people.

The cause of Takayasu’s arteritis is unknown. The clinical features can be broadly categorized into two groups: those caused by systemic inflammation and those caused by vascular damage. In the prepulseless or early phase, the diagnosis is difficult. Almost half of patients experience constitutional symptoms including fatigue, weight loss, and low-grade fever caused by systemic inflammation. Hypertension is frequently seen secondary to aortic or renal artery involvement. With progression of the disease, ischemic symptoms caused by the vascular manifestations appear, including diminished or unequal pulses, claudication, retinopathy, lightheadedness (associated with vertebral or carotid artery dissection), and visual loss. Strokes, syncope, subclavian steal syndrome, abdominal pain, and coronary ischemia are also reported.

Early diagnosis is difficult because symptoms are nonspecific and there is no specific laboratory test. Disease activity may be subclinical and not recognized by laboratory markers in up to half of cases. Later, pulses may be unequal, bruits may be auscultated, and there may be blood pressure differ-
ences in the extremities. Definitive diagnosis is made with arteriography demonstrating stenotic lesions, poststenotic dilation, aneurysms, and increased collateral circulation.

Treatment with prednisone 1 mg/kg/day for 1 to 3 months induces remission in up to 60% of patients. Other cytotoxic agents, such as methotrexate, cyclophosphamide, or azathioprine, or tumor necrosis factor modulatory therapy may be added to achieve remission if relapses occur. Infections may complicate therapy. Complications of Takayasu’s arteritis, such as hypertension, congestive heart failure, angina, or aortic regurgitation, may benefit from other forms of medical therapy. Hypertension may be treated with calcium channel blockers and angiotensin-converting enzyme inhibitors, although this may be especially difficult in patients with extensive disease who may have two or more arterial beds with substantially different blood pressures. Antiplatelet agents may be of benefit. Bypass grafting and endarterectomy are useful in patients with significant disease. Mortality has resulted mainly from renal failure, cardiac failure, or infectious complications of immunosuppressive treatment.

Medium Vessel Vasculitides

Polyarteritis Nodosa

Polymyositis nodosa (PAN) is a necrotizing vasculitis of predominantly medium-sized arteries. Immune deposits are minimal or absent, and test results for anti-neutrophil cytoplasmic antibodies (ANCAs) are typically negative. A distinction has been made between PAN and microscopic polyangiitis (MPA). PAN includes vasculitis associated with nervous system and gastrointestinal tract involvement, whereas MPA is positive for ANCAs directed at myeloperoxidase and is associated with nerve, glomerular, and lung tissue. The etiology of PAN is unknown. Viral hepatitis B or C is associated with a vasculitis identical to PAN but is treated differently, and PAN is excluded if chronic hepatitis B or C is found. PAN is also linked with drug reactions, serum sickness, and HIV. Patients with classic PAN can be any age, including children, but the peak age at onset is in the fifth or sixth decade, and there is an approximately 2:1 male-to-female ratio. Reported annual incidence rate of PAN ranges from 2 to 9 cases per 1 million people.

The early clinical picture consists of constitutional symptoms including fever, malaise, arthralgias, and myalgias. Cutaneous manifestations occur in up to one third of patients, usually seen as areas of palpable purpura, sometimes with ulceration. Frequent sites include the fingers, the ankles around the malleoli, and the pretibial areas. In severe cases, there may be widespread digital cyanosis secondary to ischemia. Splinter hemorrhages and livedo reticularis are also commonly observed. PAN can progress to peripheral neuropathy and bowel ischemia, and it can cause hypertension related to renal artery inflammation.

The diagnosis is made by the clinical pattern and histopathology seen on biopsy. After endocarditis and concomitant infections are ruled out as a cause of the vasculitis, biopsy of the involved segment may reveal the diagnosis, although the irregular distribution of the disease can make obtaining a diagnostic biopsy difficult. Probably the most common biopsy site is the sural nerve. In patients with a neuropathy, especially if the sural nerve conduction is abnormal, the biopsy finding is positive in more than 80% of cases. Mesenteric angiography may be useful to demonstrate widespread aneurysms, but these may not be present early in the course of the illness.

PAN is treated with corticosteroids, especially in cases without organ involvement. Patients with organ involvement may need additional therapy with immunosuppressive agents such as cyclophosphamide. Active viral hepatitis, if present, should be treated with antiviral therapy.

Buerger’s Disease

Buerger’s disease, also known as thromboangiitis obliterans, is an inflammatory vaso-occlusive disease that primarily affects the lower extremities in young adult male cigarette smokers, although women may also be affected. The role of tobacco, especially cigarette smoking, is clear, but the pathogenesis is unknown.

In most cases, Buerger’s disease is limited to small arteries and veins of the distal extremities. The disease typically begins with bilateral pain and ischemia of both lower extremities. At onset, the symptoms may be mild, such as paresthesias or pain only with exposure to cold, but most cases rapidly progress to a painful condition with digital cyanosis and severe claudication. Digital ulcers often occur with minor trauma. Characteristic angiographic changes include multiple bilateral areas of narrowing or occlusion in the digital, palmar, planter, ulnar, radial, and peroneal arteries. The disease must be differentiated from premature atherosclerosis and other rheumatic diseases.

Treatment consists of abstinence from all forms of tobacco. Affected limbs must be protected from trauma and cold. Calcium channel blockers and pentoxyfylline have reportedly been beneficial in some patients. Therapy using transfer of the gene for vascular endothelial growth factor is under investigation. Approximately half of individuals who continue to smoke will require amputation, often multiple times as more proximal vessels become involved.

Small Vessel Vasculitides

Behçet’s Disease

Behçet’s disease is a chronic relapsing vasculitis characterized by oral and genital ulceration; cutaneous lesions; and ophthalmologic, neurologic, or gastrointestinal manifestations. The prevalence of Behçet’s disease ranges from 1 in 1000 in Japan to 1 in 150,000 in the United States and Europe. It affects men more often than women, mainly young adults, with age of onset of 25 to 35 years. In Japan, it has been linked to histocompatibility antigen HLA-B5. Behçet’s disease is one of the rare forms of vasculitis also capable of affecting large vessels.

Oral ulceration is the hallmark of the disease, tends to be the earliest manifestation, and is required for the diagnosis of Behçet’s disease. Genital aphthae occur slightly less often than oral ulceration. The frequency of eye involvement is approximately 70% and includes bilateral or unilateral iritis, uveitis, and optic neuritis, all of which can lead to blindness. An additional hallmark of Behçet’s disease, a hypopyon uveitis, is seen rarely. CNS vasculitis, resulting in meningoencephalitis, intracranial hypertension, or a multiple sclerosis–like syndrome, may develop in 10 to 20% of patients. Gastrointestinal ulceration, including ileoceleal perforation, has been reported in Japanese patients. Skin lesions, including erythema nodosum and cutaneous vasculitis, may occur. Cardiac and renal involvement is rare. Nondeforming arthritis involving the knees and ankles has been described. Laboratory examination is nonspecific.

The diagnosis of Behçet’s disease is made when a consistent clinical syndrome is associated with a nonnecrotizing perivascular infiltrate of lymphocytes and monocytes on biopsy of affected tissue. Therapeutic options should be based on the
degree of involvement. 78 Patients with mucocutaneous lesions only may be treated with intralesional topical or aerosolized (not inhaled) corticosteroids. Topical tacrolimus can also be used, often in combination with topical corticosteroids. Patients with more severe mucocutaneous involvement may be treated with thalidomide. Systemic involvement is generally well controlled with glucocorticoids at 1 mg/kg/day. Gastrointestinal disease can be controlled with sulfasalazine 2 to 6 g/day. Patients with eye involvement should be referred to an ophthalmologist because the most common cause of morbidity is ocular involvement, which can cause blindness. Serious manifestations of uveitis and CNS involvement warrant use of azathioprine or cyclophosphamide, and patients should be admitted to the hospital. Deep vein thrombosis associated with Behçet’s disease rarely results in pulmonary emboli but should be treated with systemic anticoagulation.

Wegener’s Granulomatosis

Wegener’s granulomatosis (WG) is a necrotizing granulomatous vasculitis involving the respiratory tract, kidneys, and, to varying degrees, the medium to small vessels in other organs. Based on the National Hospital Discharge Survey, the 1986 to 1990 period prevalence of WG was estimated to be approximately 3 per 100,000 people. Both sexes were equally represented. The mean age at onset was 45 years, and most patients were white (80.9%). 77

Patients first complain of upper respiratory tract symptoms with sinusitis, otitis, and nasal ulceration. Destruction of the sinus walls may also occur. Lower respiratory tract symptoms include cough, dyspnea, hemoptysis, and asymptomatic pulmonary infiltrates, occasionally with cavitation. Tracheal stenosis occurs in 13% of patients. 78 Renal involvement is a later finding with glomerulonephritis, which may be aggressive in 85% of patients. 79,80 Eye involvement includes conjunctivitis and scleritis caused by granulomatous deposition in the sclera. Skin lesions include ulcers, nodules, and granuloma formation. Neurologic involvement is rarely a presenting feature of WG, but it may develop during the course of disease in 22% to more than 50% of cases 81,82 and includes cerebral vasculitis, granulomatous deposition in cranial nerves, and peripheral nerve vasculitis resulting in neuropathies. Coronary vasculitis, pericarditis, and conduction defects are rare. 78,83

Laboratory examination includes findings of a markedly elevated ESR, normochromic normocytic anemia, and, occasionally, thrombocytopenia. Urinalysis may show hematuria, active sediment excretion, proteinuria, and red blood cell casts. Antibodies against cytoplasmic components of polymorphonuclear cells (c-ANCA) have been found to be sensitive and specific for a diagnosis of WG. 79 ANAs are usually absent. The chest x-ray study shows multiple sharply demarcated nodular densities, predominantly in the lower lung fields, with pleural effusions in 25% of patients. 78 Lymphadenopathy is rarely seen on radiography.

Diagnosis of WG is confirmed by lung biopsy. Transbronchial biopsies are rarely diagnostic (<7%), whereas open lung biopsies reveal various combinations of vasculitis, granulomas, and necrosis in approximately 90% of cases. 78,84

Treatment with corticosteroids alone does little to alter the prognosis. Until 20 years ago, WG had a mortality rate of 80% at 1 year. 78 The use of cyclophosphamide and corticosteroids in combination induced remissions in up to 90% of patients. 78 Complications of this therapy include increased risk of infection, especially disseminated herpes zoster and Pneumocystis carinii pneumonia. Patients with known WG with flares of renal disease should be admitted for intravenous corticosteroid administration. Patients suspected to have WG should be admitted for diagnosis and possible therapy. Renal transplantation has been successful in patients who progress to end-stage renal disease.

Lymphomatoid granulomatosis, often confused with WG, is characterized by destructive infiltration of lymphocytoid and plasmacytoid cells. The lower respiratory tract disease is the most prevalent, and upper respiratory tract involvement is rarely seen. Involvement of the kidney with deposition of granuloma is rare; however, in contrast to findings in WG, no vasculitis or glomerulonephritis is present. The spleen, lymph nodes, and bone marrow are usually spared. Malignant lymphoma develops in 50% of patients. 80 There are no specific laboratory findings, although in contrast to that in WG, the ESR is usually normal or only mildly elevated and the c-ANCA is negative. The chest x-ray study shows multiple nodules similar to those seen in metastatic cancer. Diagnosis is made by biopsy, usually of lung tissue. Treatment is the same as for WG. Remissions with corticosteroids and cyclophosphamide are seen in 50% of patients, except in those who are also diagnosed with malignant lymphoma, in whom mortality is 90%. 80

Churg-Strauss Syndrome

Churg-Strauss syndrome (allergic granulomatosis and angiitis), first described in 1951 by Churg and Strauss, is characterized by granulomatous vasculitis of multiple organs, with hypereosinophilia in patients with asthma and allergic rhinitis. The etiology of Churg-Strauss syndrome is not known, but there is a definite association with allergy and atopic disorders. Nearly 70% of patients have a history of allergic rhinitis, often associated with nasal polyposis, and the association with asthma, usually adult onset, is part of most case definitions. 80 The vasculitis usually involves the veins and venules of the lower respiratory tract. The annual incidence of Churg-Strauss syndrome is approximately 2.4 cases per 1 million individuals. 80 The mean age is 44 years, with men affected more often than women.

Patients have systemic symptoms of fever, weight loss, and malaise. Pulmonary symptoms are predominant, with a history of asthma for at least 2 years before diagnosis. 85 Skin lesions occur in 60 to 70% of patients, with subcutaneous nodules or palpable purpura present. Pericarditis can lead to constrictive pericarditis. The Churg-Strauss syndrome is the ANCA-associated vasculitis most likely to involve the heart, usually in the form of heart failure. 86 Gastrointestinal symptoms caused by infiltration of the small bowel or stomach walls are associated with infarction, perforation, or bloody diarrhea. Renal disease is much less prominent. The neurologic manifestation is mainly mononeuritis multiplex, found in up to 80% of patients. 86

Laboratory examination reveals a persistent eosinophilia greater than 1500/mm³, often up to an absolute count of 5000 to 20,000/mm³. 86 There is no definite correlation between eosinophilia and disease activity. Patients may have anti-neutrophil cytoplasmic antibodies directed against myeloperoxidase (p-ANCA). The chest x-ray study can show patchy, fleeting infiltrates known as Löeffler’s syndrome, consolidation, or cavitation.

The diagnosis of Churg-Strauss syndrome is made by biopsy, usually of skin or lung tissue. The patient may also have an elevated immunoglobulin E. Churg-Strauss syndrome is extremely responsive to corticosteroids, with usual dosing of prednisone at 60 mg/day orally. The prognosis is much improved with treatment, with 5-year survival greater than 50% in contrast to 25% in untreated patients. Nevertheless, certain disease complications, particularly the presence of
vasculitic neuropathy, cardiac involvement, or glomerulonephritis, should trigger the use of cyclophosphamide as part of the remission induction strategy.89

**Microscopic Polyangitis**

Microscopic polyangiitis is a systemic neutrophilic small vessel vasculitis most often associated with rapidly progressive renal disease. MPA is the most common cause of the pulmonary-renal syndrome of alveolar hemorrhage and glomerulonephritis. There has been increasing recognition of this disorder in the United States since the 1994 Chapel Hill Consensus Conference on the nomenclature of systemic vasculitides because many cases before then were considered to be forms of polyarteritis nodosa. MPA has an estimated annual incidence of 4 cases per 1 million. MPA occurs in people of all ethnic backgrounds, but epidemiologic studies in the United States demonstrate a predilection for whites. The male-to-female ratio is approximately 1:1. The typical patient is middle-aged, but the disease may affect people of all ages.90

The term “polyangiitis” is preferred to “polyarteritis” for MPA because of the tendency of the disease to involve veins as well as arteries. Several studies have attempted to elucidate environmental factors associated with the onset of MPA. Seventy percent of patients with MPA have ANCAs, and anti-MPO antibodies are also detected. The five most common clinical manifestations of MPA are glomerulonephritis (nearly 80% of patients), weight loss (>70%), mononeuritis multiplex (60%), fevers (55%), and a variety of cutaneous findings (>60%). In contrast, alveolar hemorrhage occurs in a comparative minority (12%).90

MPA usually requires both glucocorticoids and a cytotoxic agent to control disease. The usual regimen to induce remission in patients with severe organ involvement includes high doses of prednisone (often preceded by a 3-day “pulse” of methylprednisolone, 1 g/day) plus cyclophosphamide. Following the induction of remission, patients may be switched to either azathioprine (up to 2 mg/kg/day) or methotrexate (up to 25 mg/week, assuming that residual renal dysfunction does not preclude this medication). Plasma exchange has also been shown to be useful. If MPA is diagnosed early and treated promptly, patients have a high likelihood (>90%) of achieving disease remission, although approximately one third of patients suffer disease flares after the achievement of remission.91

**Goodpasture’s Syndrome**

Goodpasture’s syndrome, or anti-glomerular basement membrane disease (anti-GBM), is characterized by the linear deposition of anti-glomerular basement membrane antibodies in the glomerular and alveolar basement membranes resulting in alveolar hemorrhage and progressive glomerulonephritis. Environmental factors and genetic susceptibility are thought to play a role, but no clear etiology has been identified. All age groups are affected. In adults, the mean age of onset is 20 to 30 years, with a peak incidence in young men age 20 to 30 years. A second peak occurs in those age 50 to 70 years, with men and women equally affected. The annual incidence is estimated to be 1 case per 2 million people of white European descent.92

General malaise, weight loss, fever, or arthralgia may be the initial features of anti-GBM disease. Patients may also have cough, dyspnea, and hemoptysis. The principal clinical features of the disease are development of renal failure due to progressive glomerulonephritis or pulmonary hemorrhage. Historically, hemoptysis has been the most common presenting feature, occurring in approximately 70% of reported cases.92

Initially, the pulmonary hemorrhage may be mild, or it may be severe and life threatening. Hypoxia is common. The renal manifestations are varied; some patients have normal renal function, whereas others have a rapidly progressing glomerulonephritis. Patients may also have skin involvement with palpable purpura. Laboratory examination is notable for elevated ESR and urinalysis with red blood cell casts. On blood testing, anti-GBM antibodies can be measured, but the level of circulating antibodies does not correlate with the severity of the disease. Complement levels are normal, and in contrast to findings in Wegener’s granulomatosis, c-ANCA tests are negative. A chest radiograph shows hilar pulmonary infiltrates.

The differential diagnosis includes SLE and Wegener’s granulomatosis. Diagnosis is made by renal biopsy. Lung tissue shows pulmonary alveolar hemorrhage, with similar linear deposition of antibodies along the alveolar basement membrane.

Management of the airway is the first priority in patients with severe pulmonary hemorrhage. Treatment with methylprednisolone 10 to 15 mg/kg IV is necessary if rapidly progressive glomerulonephritis or severe pulmonary hemorrhage complicates the patient’s course. The use of cytotoxic agents such as cyclophosphamide, as well as plasmapheresis (2–4 L/day of plasma), has been associated with improvement in pulmonary hemorrhage and glomerular lesions if extensive renal damage has not already occurred. Patients who progress to end-stage renal disease are candidates for transplantation if anti-GBM antibodies return to undetectable levels with treatment; otherwise, the disease may recur in the transplanted kidney.93 Some patients present with the occasional flare of pulmonary hemorrhage. These patients should be admitted to the hospital to be observed for airway complications and for development of renal disease. The prognosis is varied but has greatly improved in the past 15 years because plasma exchange has been used more aggressively.

**Henoch-Schönlein Purpura**

Henoch-Schönlein purpura (HSP) is a small vessel vasculitis involving the skin, gut, and kidney and is characterized by immunoglobulin A (IgA)-dominant immune deposits in target organs. This vasculitis is particularly common in children, although patients of any age can be affected. The annual incidence in children is approximately 15 cases per 100,000 children.94 The male-to-female ratio is 2:1. The syndrome occurs most often in the winter and early spring; two thirds of the cases follow an upper respiratory tract infection, with onset an average of 10 days after the start of respiratory symptoms.95 Other inciting agents associated with HSP include insect stings and drugs.

The classic full presentation includes the acute onset of fever, palpable purpura on the lower extremities and buttocks, abdominal pain, arthritis, and hematuria. The rash is accompanied by arthralgias of the lower extremities, most commonly the ankles, with swollen, tender joints. The rash can be urticarial or purpuric and is usually in the lower extremities (Fig. 116-2). Frank arthritis is usually absent. Gastrointestinal complaints, seen in 70% of patients, include abdominal pain, nausea, vomiting, and diarrhea with blood and mucus per rectum.96 Renal involvement occurs in 50% of patients with hematuria and red blood cell casts; however, it rarely progresses to renal failure.97 Nervous system involvement is rare, especially in children. The syndrome is relapsing and remitting over several weeks.

Antigens to drugs, infectious agents, food, insect bites, and immunizations have been implicated in the pathogenesis of the IgA-dominant immune deposition. Treatment of the
precipitating infection or discontinuation of the inciting drug is necessary. The treatment of HSP is an area with little evidence but much ongoing investigation.96 NSAIDs may alleviate arthralgias but can aggravate gastrointestinal symptoms and should be avoided in any patient with renal disease. Dapsone may be effective in cases of HSP, possibly through interference with the interactions of IgA and neutrophils. Children with more severe arthralgias and abdominal pain benefit from prednisone at 1 mg/kg/day orally. Adults who have symptoms may be given prednisone 60 mg/day. Glucocorticoids do not appear to improve the rash, and their effectiveness in renal disease is controversial. Uncontrolled trials suggest that high-dose methylprednisolone followed by oral prednisone or renal disease may recur in up to 33% of patients. A small percentage of patients do well with supportive care because HSP follows a self-limited course, resolving without substantial morbidity. The vast majority of cases resolve within 6 to 8 weeks. The disease may recur in up to 33% of patients. A small percentage of patients have prolonged renal impairment.95

Hypersensitivity Vasculitis

Hypersensitivity vasculitis, also known as cutaneous leukocytoclastic angiitis, is a small-vessel vasculitis that is restricted to the skin and not associated with any other form of primary or secondary vasculitis. It can be seen at any age and has no gender predominance. The etiology is often unknown, although drugs seem the most commonly identifiable offender.97 Vaccinations have more rarely been associated with hypersensitivity vasculitis. Onset can be abrupt after exposure to the etiologic agent, but it usually ranges from 7 to 21 days after initial exposure. Although almost any medication can be associated with a hypersensitivity vasculitis, certain classes of drugs are more commonly associated with a hypersensitivity vasculitis (Box 116-5).98 In up to 40% of cases, however, no specific cause is identified.99

The skin lesions of hypersensitivity vasculitis include purpura (either palpable or nonpalpable), papules, urticaria/angioedema, erythema multiforme, vesicles, pustules, ulcers, and necrosis. The lesions typically occur first and most prominently in dependent regions (i.e., the lower extremities or buttocks). The lesions tend to occur in cohorts or “crops” that are the same age. The occurrence of the lesions may be asymptomatic but is usually accompanied by a burning or tingling sensation. Arthralgias and even frank arthritis, with a predominance for large joints, are sometimes present. Laboratory examination is nonspecific, with a mildly elevated ESR and mild leukocytosis. The pathologic finding in the vessels, primarily the postcapillary venules, is immune complex deposition with infiltration by polymorphonuclear leukocytes with or without destruction of vessel walls. Hypersensitivity vasculitis must be distinguished primarily from other small vessel vasculitides, from autoimmune inflammatory conditions associated with joint disease and rashes, and from other cutaneous reactions to medications.

Treatment includes discontinuation of the offending agent. In mild cases, symptomatic treatment may be needed. For more severe involvement, corticosteroids (40–60 mg of prednisone per day gradually tapering the dose) are indicated.100

Mixed Cryoglobulinemia

Cryoglobulins are immunoglobulins and immune complexes that precipitate in the cold (4°C) and dissolve on rewarming. Mixed cryoglobulinemia syndrome is a consequence of immune complex-mediated vasculitis and is characterized by a typical clinical triad of purpura, weakness, and arthralgias. Middle-aged women are most commonly affected. Precipitatin-
ing antigens include hepatitis A, B, and C; cytomegalovirus; or Epstein-Barr virus.\textsuperscript{101}

The clinical features of mixed cryoglobulinemia include leukocytoclastic vasculitis (manifested as palpable purpura), polyarthralgias and arthritis, lymphadenopathy, hepatosplenomegaly, peripheral neuropathy, and hypocomplementemia, especially decreased C\textsubscript{4} serum levels. Recurrent palpable purpura occurs in virtually all patients. The most serious involvement is renal deposition of the cryoglobulins, resulting in glomerulonephritis, and it occurs in 20 to 60\% of patients.\textsuperscript{102}

Patients may have fulminant or slowly progressive chronic renal disease. Laboratory examination demonstrates an elevated ESR, decreased serum complement levels, and the presence of cryoglobulins.

Diagnosis is made clinically in the presence of cryoglobulins; however, it may be difficult to distinguish from SLE or HSP. Treatment depends on the extent of involvement. Patients with disease limited to the skin may try low-dose steroids, and patients with systemic manifestations are usually started on prednisone 60 mg/day orally, although low-dose steroids should be avoided during initial antiviral therapy. Cyclophosphamide has been helpful in controlling systemic disease and allows decreases in steroid dosages. Approximately 75\% of patients with mild to moderate hepatitis C-associated cryoglobulinemic vasculitis respond to antiviral therapy initially, but sustained responses are low.\textsuperscript{103} Plasmapheresis has also been used in life-threatening cases but often requires concomitant immunosuppressive treatment. Rituximab, an anti-CD20 monoclonal antibody that depletes B cells, is also being explored as a therapeutic agent.

Serum Sickness

Serum sickness is a type III hypersensitivity reaction that results from injection of foreign proteins or serum. Reactions secondary to the administration of nonprotein drugs are clinically similar to serum sickness reactions. Not all substances that are recognized as foreign will elicit an immune response. The antigen must be of characteristic size or have specific antigenic determinants and physiological properties to be an effective stimulator of the immune system. After an appropriate antigen is introduced, an individual’s immune system responds by synthesizing antibodies. The antibody reacts with the antigen, forming soluble circulating immune complexes that may diffuse into the vascular walls, where they may initiate fixation and activation of complement. Complement-containing immune complexes generate an influx of polymorphonuclear leukocytes into the vessel wall, where proteolytic enzymes that can mediate tissue damage are released. Immune complex deposition and the subsequent inflammatory response are responsible for the widespread vasculitic lesions seen in serum sickness.

Serum sickness has distinctive skin findings. Typically, erythema first occurs on the sides of the fingers, toes, and hands, before a more widespread eruption that is most often morbilliform (in two thirds of patients), sometimes with urticaria. Urticaria is seldom seen alone. Approximately half the cases of serum sickness have visceral involvement. Rash, fever, constitutional symptoms, arthralgia, and arthritis are the most frequent clinical findings.\textsuperscript{104} Usually, symptoms start 12 to 36 hours after ingestion if there is a previously immunizing exposure, but they may occur up to 7 to 21 days after antigen exposure. The manifestations seen in serum sickness are due to immune complex deposition but not to systemic vasculitis as described in this chapter. In serum sickness, serum C\textsubscript{3} and C\textsubscript{4} complement levels are markedly decreased.\textsuperscript{105} Withdrawing the drug usually leads to rapid resolution. Treatment is supportive with antihistamines and antipyretics. Systemic corticosteroids may benefit some patients. Symptoms usually last 1 or 2 weeks before spontaneously subsiding. Long-lasting sequelae generally do not occur.

**Erythema Nodosum**

Erythema nodosum is a vasculitis of the venules in the subcutaneous layers of the skin. The cause is unclear, but it is usually the result of a hypersensitivity vasculitis from infections, drugs, or a systemic disease. The disease is seen most commonly in spring and fall. The incidence of erythema nodosum is approximately 1 to 5 per 100,000 people. Women are more commonly affected than men, with a male-to-female ratio of 1:6. The peak incidence is in the third decade of life.\textsuperscript{106,107} Erythema nodosum is thought to be caused by a circulating immune complex-mediated process, although the exact pathogenic process is not clear.

The hallmark lesions of erythema nodosum are tender erythematous subcutaneous nodules that have a blue hue as they resolve (Fig. 116-3). Symmetrical pretibial involvement is most common, although the extensor surfaces of the forearm, thigh, and trunk may also be affected. Patients may have just the nodules or may have systemic symptoms, including fever and malaise. Arthralgias are seen in 90\% of patients at some time during the disease course and have been known to persist for up to 2 years after resolution.\textsuperscript{107}

Erythema nodosum is usually idiopathic, although patients who have erythema nodosum should be considered for underlying diseases such as viral upper respiratory tract infection, streptococcal infection, sarcoidosis, tuberculosis, and drug exposure. Much rarer causes include inflammatory bowel diseases, histoplasmosis, *Yersinia*, *Salmonella*, *Chlamydia*,

![Figure 116-3.](Image)

The hallmark lesions of erythema nodosum are tender erythematous subcutaneous nodules that have a blue hue as they resolve. (From Habif TP: Clinical Dermatology, 4th ed. New York, Mosby, 2004.)
coccidiomycosis, psittacosis, and autoimmune diseases such as SLE. Drugs implicated include penicillins, sulfa drugs, aspartame, phenytoin (Dilantin), and oral contraceptives. The eruption can last up to 6 weeks. Although the lesions are exquisitely tender, erythema nodosum tends to be self-limited. The most common approach is treatment of any underlying disorder and supportive therapy. NSAIDs may be useful in controlling the arthralgias. Disposition depends on suspicion of underlying disease but is usually outpatient follow-up.

**Panniculitis**

The panniculitides are a group of heterogeneous inflammatory diseases involving the subcutaneous fat. Biopsy of the involved subcutaneous tissue shows fat cell necrosis, infiltration of inflammatory cells with macrophages, and vasculitis. Several forms of panniculitis exist. The inflammatory infiltrate can involve the septa or the lobule, and vasculitis may or may not be present. Diseases associated with panniculitis are erythema nodosum, erythema induratum, lupus profundus, pancreatitis, superficial thrombophlebitis, α1-antitrypsin deficiency, light-chain paraproteinemia, and C1 inhibitor deficiency.108

Erythema nodosum can exist as a manifestation of systemic disease or as a hypersensitivity to drugs (as discussed previously). Erythema induratum (Bazin’s disease) and nodular vasculitis are synonymous terms used to describe a vasculitis of the skin of the calf associated with tuberculosis. Typical erythema induratum is a disease of middle-aged women in whom erythematous subcutaneous nodules and plaques appear on the posterior aspects of the lower leg. The bilateral lesions are usually tender and begin as nodules but then ulcerate and scar. The course is protracted and recurrent episodes over years or decades are common. Mycobacteria are rarely found in the lesions. Therapy is supportive with dressing changes and elevation, unless evidence of active tuberculosis is found elsewhere.109

Lupus profundus is a chronic recurrent panniculitis that appears in approximately 1 to 3% of patients with cutaneous lupus erythematosus. Patients have subcutaneous nodules in the scalp, face, breasts, thighs, and buttocks. The lesions ulcerate and then heal. The differential includes erythema nodosum, but lupus profundus the lesions are usually more chronic and nontender.

Superficial thrombophlebitis presents with erythematous, tender subcutaneous nodules with a linear arrangement along a tender cordlike thickening of the involved vein. Usually, these cords are located on the lower limbs and are associated with venous insufficiency. Although a primary or secondary hypercoagulable state should be investigated, most of the time venous insufficiency of the lower extremities is usually the only precipitating factor. Treatment of thrombophlebitis is conservative, with application of a support stocking on the involved leg. In chronic and recurrent cases, especially those associated with malignancy, heparin, and fibrinolytic drugs may be used.110

**KEY CONCEPTS**

**Systemic Lupus Erythematosus**

- Patients with SLE can have multiple and varied symptom complexes. The diagnosis should be considered in patients with fever, rash, or unexplained systemic complaints.
- Patients with deep vein thrombosis without risk factors should be considered for APS. Patients with evidence of thrombosis should receive anticoagulation and be admitted for further workup.
- Febrile patients with SLE receiving immunosuppressive therapy should be hospitalized and treated aggressively because they have a high risk for gram-negative or streptococcal sepsis.
- Patients with worsening renal function or with involvement of the heart, lungs, or CNS should be hospitalized for aggressive treatment to prevent progression of the disease and symptoms.
- Patients with symptoms of coronary ischemia should be aggressively treated. Even young patients with risk factors for CAD should be evaluated for coronary ischemia.

**The Vasculitides**

- The diagnosis of systemic vasculitis is difficult and should be considered in patients with rash and pulmonary or renal complaints.
- Consultation with a rheumatologist is helpful for determining management when patients have flares of a known vasculitis.
- Febrile patients receiving immunosuppressive therapy or corticosteroids have a high risk for sepsis or disseminated viral infections and should be treated aggressively.

Chapter 117

PERSPECTIVE

Over millions of years, the human immune system has evolved to become a highly complex, elegant, and efficient organ whose chief function is to protect the human host (self) from harmful offenders (nonself). Antigens are foreign (or self) molecules that will elicit an immune response. Immunologic responses to antigens in humans are coordinated by two immune systems: the ancient innate immune system, which humans inherited from invertebrates, and the recently evolved adaptive immune system, which is present in humans and vertebrates. The innate system is considered the first line of defense. Its effector components include mast cells, macrophages, dendritic cells, natural killer cells, granulocytes, antimicrobial peptides, complements, and cytokines. Encoded in the germline, receptors in the innate immune system can recognize foreign molecular patterns that are highly conserved in microbes but not in humans, and they immediately begin the process of clearing the antigens. The adaptive system, on the other hand, must allow time for the antigen-specific cells (B and T cells) to amplify through a process known as clonal expansion to mount an effective immune response. Its effector components include B and T lymphocytes and cytokines. The adaptive immune system is characterized by having an immune memory and enormous diversity, capable of recognizing the myriad antigens through a vast library of antibodies and receptors (up to \(10^{15}\)). This diversity of antigen receptors is achieved by somatic rearrangement of fewer than 400 genes. Despite the complexity, the two immune systems work in concert and with great fidelity to provide the human host immunity. However, they can overreact, causing allergic disease.

For practical purposes, the term allergy is used herein to refer to an IgE-mediated (also known as type I or immediate) hypersensitivity reaction. Antigens that elicit an allergic reaction are referred to as allergens. Cases of allergy and anaphylaxis have historically been documented to the days of antiquity. Pharaoh Menes died of anaphylaxis in 2641 BCE. In 1902, Portier and Richet discovered that although a dog tolerated an injection of sea anemone toxin the first time, it died within minutes when injected again several weeks later. They coined the term anaphylaxis from Greek (a, against; phylax, guard or protect), meaning “against protection.” For this and subsequent work in anaphylaxis, Richet was awarded the Nobel Prize in Medicine and Physiology in 1913. Today, anaphylaxis refers to a life-threatening allergic syndrome (i.e., IgE-mediated) characterized by multiorgan involvement and rapid onset. Patients having an anaphylactic reaction would typically present in distress with prominent pruritic urticaria, orolaryngeal edema, bronchospasm, hypotension, and central nervous system and gastrointestinal (GI) symptoms. Common allergens that can induce an anaphylactic reaction include drugs, foods, insect stings, and latex. Deaths from anaphylaxis usually result from acute respiratory failure or cardiovascular collapse. Prompt recognition and aggressive treatment in the emergency department (ED) can usually stave off this potentially life-threatening allergic reaction. The term anaphylactoid reaction refers to a syndrome clinically similar to anaphylaxis that is not mediated by IgE. Its clinical presentation and treatment are identical to those of anaphylaxis. Anaphylactoid reactions seem to result from direct degranulation of mast cells (and basophils) and may follow a single, first-time exposure to certain inciting agents. In this chapter, the term anaphylaxis is used to refer to both IgE- and non-IgE-mediated reactions, obviating the need for the term anaphylactoid reaction.

Definition, Epidemiology, and Risk Factors for Anaphylaxis

Although anaphylaxis has traditionally been considered a clinical syndrome, there has been no universal agreement on a clinical definition of an anaphylactic reaction; anaphylaxis is usually defined in mechanistic terms as an IgE-mediated event. In an attempt to provide a working definition that clinicians can apply in the clinical setting, the National Institute of Allergy and Infectious Disease, in collaboration with the Food Allergy and Anaphylaxis Network, advanced a set of clinical criteria for identifying and diagnosing anaphylaxis (Box 117-1). In the most common scenario encountered in the ED, the diagnosis of anaphylaxis is considered “highly likely” if a patient presents with acute onset (within minutes after an exposure) of rash or mucosal swelling and respiratory insufficiency or hypotension.

The epidemiology of anaphylaxis is not known with certainty, and estimates in medical literature vary widely. As a measure of risk, the annual incidence rate for all-cause anaphylaxis is generally believed to be 21 per 100,000 person-years; the case mortality in this series is 0.65%. As a measure of burden of disease, the prevalence rate of anaphylaxis ranges from 1.21 to 15.04% for the U.S. population. Given the U.S. population of 272 million in 1999, these prevalence figures imply that between 3.3 million and 43 million Americans are at risk for an anaphylactic reaction. It is commonly believed that there are probably 100,000 cases of anaphylaxis per year.
Anaphylaxis is highly likely when any one of the following three criteria is fulfilled:

1. Acute onset of an illness (minutes to several hours) with involvement of the skin, mucosal tissue, or both (e.g., generalized hives, itch-flush, swollen lips-tongue-uvula)

AND AT LEAST ONE OF THE FOLLOWING:

- Respiratory compromise (e.g., dyspnea, wheeze-bronchospasm, stridor, reduced PEF, hypoxemia)
- Reduced BP or associated symptoms of end-organ dysfunction (e.g., hypotonia [collapse], syncope, incontinence)

2. Two or more of the following occurring rapidly (minutes to several hours) after exposure to a likely allergen for that patient:
   - Involvement of the skin-mucosal tissue (e.g., generalized hives, itch-flush, swollen lips-tongue-uvula)
   - Respiratory compromise (e.g., dyspnea, wheeze-bronchospasm, stridor, reduced PEF, hypoxemia)
   - Reduced BP or associated symptoms (e.g., hypotonia [collapse], syncope, incontinence)
   - Persistent gastrointestinal symptoms (e.g., crampy abdominal pain, vomiting)

3. Reduced BP after exposure to known allergen for that patient (minutes to several hours):
   - Infants and children: low systolic BP (age specific) or greater than 30% decrease in systolic BP
   - Adults: systolic BP of less than 90 mm Hg or greater than 30% decrease from that person’s baseline

Low systolic blood pressure for children is defined as less than 70 mm Hg from 1 month to 1 year, less than 70 mm Hg + 2 x age from 1 to 10 years, and less than 90 mm Hg from 11 to 17 years.

BP, blood pressure; PEF, peak expiratory flow.

PRINCIPLES OF DISEASE

Development of the Immune System and Mechanism of Immune-Mediated Injury

The adaptive and innate immune systems originate from the common pluripotential hematopoietic stem cells, which are derived from the yolk sac and later reside in the bone marrow. These stem cells differentiate and develop into the lymphoid precursor cells and the colony-forming unit for granulocyte, erythroid, myeloid, and megakaryocyte (CFU-GEMM) stem cells. The lymphoid precursor cells in turn differentiate into bursa-equivalent lymphocytes (B cells), thymus-derived lymphocytes (T cells), and natural killer (NK) cells; the CFU-GEMM cells, in the meantime, develop into mast cells, basophils, and others (Fig. 117-1). When the body encounters an allergen, the cellular components of the adaptive immune system interact with the cellular and protein components of the innate immune system to mount a concerted defense aimed at neutralizing and removing the harmful allergen.

T Cell Development

Lymphoid precursor cells migrate from the bone marrow into the thymus, where they progress through ontogeny. Under regulation by cytokines and cell-cell interaction, these precursors undergo gene rearrangement and positive and negative selection. In the process, T cells acquire the T cell antigen receptors and various surface markers and eventuate into two main T cell lineages. Using the cluster of differentiation (CD) classification, there are principally two types of mature T cells that eventuate out of the thymus: CD4, also called helper T cells, and CD8, also called suppressor T cells. Depending on the type of cytokine produced, T helper cells are subdivided into type 1 helper cells (Th1) and type 2 helper cells (Th2), with opposing activities. Whereas Th1 cells inhibit IgE production and IgE isotype switching, Th2 cells stimulate IgE production and IgE isotype switching. The balance of these stimulatory and inhibitory activities of the Th1 and Th2 cells is believed to determine an individual’s propensity to develop allergic disease or atopy and may help explain the increased prevalence of allergy in urbanized and Western societies in the past three decades. Early in utero and soon after birth, naïve T lymphocytes in the infant’s immune system are dominated by the allergy-prone Th2 cells and their associated cytokines (interleukins [ILs] 4, 5, and 13). These cytokines are administered by the mucosal route (e.g., food). Atopy does not, however, seem to be a risk factor when the allergen is administered parenterally (e.g., penicillin). Limited data tend to suggest that economic status, age, sex, and season of the year seem to affect the risks of having an anaphylactic reaction. Anaphylactic reactions seem to be more common in summer and early fall (the outdoor season), in people of higher socioeconomic status, in women older than 30 years, and in adults. The dose, frequency, duration, and route of administration of a drug also affect the tendency to develop an anaphylactic reaction, with the parenteral and topical routes more likely to lead to an anaphylactic reaction. One interesting aspect of drug-related anaphylaxis is the constancy of administration. An anaphylactic reaction may not occur in a susceptible patient as long as a drug is administered at regular intervals. The same patient may, however, experience an anaphylactic reaction if the drug is resumed after an interruption of therapy. Lastly, the more distant the last exposure, the lower the risks of anaphylaxis upon reexposure, presumably because of some forgetfulness of the immune memory.
B cell ontogeny can be divided into antigen-independent and antigen-dependent stages. During the antigen-independent stage, B cells mature in primary lymphoid organs (bone marrow and fetal liver), where they undergo gene rearrangement in a stochastic manner and acquire various surface markers. Later during the antigen-dependent stage in the secondary lymphoid organs (lymph nodes and spleen), B cells differentiate into memory B cells and plasma cells and are ready to secrete immunoglobulins. Throughout B cell ontogeny, B cell maturation, isotype switching, and immunoglobulin production are driven by activated T cells, cytokines, and interaction with antigen and bone marrow stromal cells.

Immunoglobulins are protein molecules composed of two identical polypeptide heavy chains and two identical polypeptide light chains, covalently linked by disulfide bonds (Fig. 117-2). The heavy (H) chains have one variable domain, V_H, and three or four constant domains, C_H. The light (L) chains have one variable domain, V_L, and one constant domain, C_L. The variable domains of the heavy and light chains together form a pair of identical antigen binding sites and, together with the adjacent constant heavy domain pair, make up the Fab (antibody-binding fragment) region of the immunoglobulin molecule. The remaining constant domains of the heavy chains together form the Fc (crystallizable fragment) region of the immunoglobulin molecule. The Fc binds to the surface receptors of effector cells such as mast cells, B cells, or macrophages. There are five isotypes or classes of immunoglobulins, IgG, IgA, IgM, IgD, and IgE, with isotype IgG having four subclasses (IgG1, IgG2, IgG3, and IgG4) and IgA two subclasses (IgA1 and IgA2). The body usually produces IgM antibodies when it first encounters an antigen. Repeated antigen exposure, however, may cause the constant region of the IgM to switch to another class (IgA, IgG, or IgE), a process also known as isotype switching. Isotype IgE (and IgG4) is the most important antibody in the pathogenesis of allergic disease and anaphylaxis.

**Classification of Reactions**

There are four types of hypersensitivity reactions in the Coombs and Gell classification system. Type I (immediate hypersensitivity) is IgE (and IgG4) mediated and accounts for most allergic and anaphylactic reactions observed in humans. Type II (cytotoxic) denotes antibody-mediated cytotoxic reaction. In this scheme, complement-fixing IgG (or IgM) engages cell-bound antigen, activating the classic complement pathway, leading to the fixation of membrane attack complexes and cell lysis. In the process, anaphylatoxins C3a and C5a may also cause mast cell mediators to be released, producing the same action as the classic mediators of anaphylaxis. Type III (immune complex) is IgG or IgM complex mediated. Circulating soluble antigen-antibody immune complexes migrate from the circulation to deposit in the perivascular interstitial space, thereby activating the complement system. Anaphylactic reactions to blood transfusions or blood component therapy, including serotherapy (immunoglobulin administration), are clinical examples of the overlap of type II and type III reactivity; thus, they have been classified as complement-mediated or immune complex-mediated anaphylaxis. Type IV (delayed hypersensitivity) is T cell mediated and has no documented relationship to the pathogenesis of anaphylaxis.
pletes the process known as sensitzation. These IgE-bearing mast cells usually reside in the mucosal surfaces, submucosal tissue (around venules), and cutaneous surfaces, and they are capable of becoming activated upon reexposure to a specific allergen. Cross-linking of the FcεRI on the mast cells by a specific multivalent allergen sets off a cascade of conformational and biochemical events, leading eventually to the degranulation of preformed mediators and the generation and release of arachidonic acid metabolites and cytokines from mast cells (and basophils). At the target tissue level, these mediators cause enhanced capillary permeability, vasodilation, smooth muscle contraction, sensory nerve stimulation, myocardial depression, and activation of secondary inflammatory pathways. These pathologic events result in clinical manifestations that include flushing syndrome, urticaria and angioedema, pruritus, nausea, vomiting, diarrhea, abdominal pain, chest pain, dyspnea, wheezing, respiratory insufficiency and failure, dizziness, syncope, hypotension, and shock.

**Immunoglobulin E–Mediated Signal Transduction System**

Following cross-linking of FcεRI, signal transduction is initiated by a tyrosine kinase, termed Lyn, which is constitutively associated with the FcεRI receptor (Fig. 117-3). Subsequently, Lyn phosphorylates the immunoreceptor tyrosine-based activation motif (ITAM) of the subunits of the FcεRI, leading to the activation and binding of protein tyrosine kinases (PTK) with SRC homology domain 2 (SH2). One such PTK is spleen tyrosine kinase (Syk). An activated Syk subsequently leads to further tyrosine phosphorylations of several “adapter” proteins. Principally among these are (1) the phosphorylation of linker for activation of T cells (LAT), which serves as the attachment site for several proteins including leukocyte-specific phosphoprotein of 76 kd (SLP-76), and (2) the phosphorylation of phospholipase Cγ (PLC-γ). Phosphorylated PLC-γ generates diacylglycerol (DAG) and inositol-1,4,5-triphosphate (IP3) from membrane phospholipids. DAG in turn activates protein kinase C, which promotes exocytosis of preformed granules and cytokine transcription factors. IP3 binds to receptors in the endoplasmic reticulum, causing a rise in intracellular Ca2+ and resulting in a depletion of Ca2+ store, which leads to more influx of calcium from extracellular space via the activation of the Ca2+ release-activated Ca2+ channel (ICRAC). Spikes in intracellular calcium activate a number of calcium-gated kinases, including phospholipases, which cleave membrane phospholipids to generate lysophospholipids, which in turn facilitate the fusion of secretory granules with the cell membrane, leading to the exocytosis of the secretory granules. Through the LAT/SLP-76 multimolecular complex, tyrosine phosphorylation and activation of a number of enzymes and adapters lead to the activation of JNK and ERK (among others) and ultimately the synthesis and release of cytokines and arachidonic acid (AA) metabolism. The end result is the secretion of preformed mediators, AA metabolites, and cytokines (Box 117-2) into the circulation, which act on target organs to cause the clinical syndrome of anaphylaxis.

**Mediators of Anaphylaxis**

The mediators released by the mast cells and basophils can be categorized into three main groups: preformed mediators, lipid-derived metabolites (AA metabolism), and cytokines (see Box 117-2). Of the preformed mediators, histamine is the most...

CCL, CC chemokine ligand; GM-CSF, granulocyte-macrophage colony-stimulating factor; IL, interleukin; LTB*4, leukotriene B*4; PGD*2, prostaglandin D*2.

Physiologic Effects

The chemical mediators released from mast cells exert their effect on various target organs to produce the clinical syndrome of anaphylaxis. Increased vascular permeability can lead to urticaria, angioedema, laryngeal edema, nasal congestion, or gastrointestinal swelling with abdominal cramping and lethality associated with anaphylaxis. In contrast to the preformed mediators, cytokines and lipid metabolites are elaborated following the activation of mast cells and basophils (see Fig. 117-3). Prostaglandin D*2 (PGD*2) is the main AA metabolite released by activated mast cells (but not basophils). PGD*2 (and thromboxanes) is synthesized from AA by the cyclooxygenase pathway (via both COX-1 and COX-2). PGD*2 is responsible for causing hypotension, inhibition of platelet aggregation, and bronchospasm; PGD*2 is approximately 30 times more potent than histamine in causing bronchoconstriction. The leukotrienes—LTB*4, LTC*4, LTD*4, and LTE*4—also referred to as cysteinyl leukotrienes or slowreacting substances of anaphylaxis, are synthesized from AA via the lipooxygenase pathway. LTB*4 and LTC*4 are first synthesized intracellularly in mast cells and basophils and then secreted; LTC*4 is subsequently converted to LTD*4 and LTE*4 in the extracellular space (by gamma-glutamyl transpeptidase and dipeptidase). They are involved in cholinergic-independent bronchospasm, increased vascular permeability, and increased mucous gland production. These cysteinyl leukotrienes have a slow onset but are 10 to 1000 times more potent than histamine in causing bronchoconstriction when administered by aerosol. They also have a longer duration of action and potentiate the effects of other bronchoconstrictors such as histamine.

Platelet-activating factor (PAF) is an unstored phospholipid and the most potent compound known to cause aggregation of human platelets with subsequent release of platelet-derived vasoactive mediators. Its other actions include neutrophil activation and chemotaxis and ileal and parenchymal lung strip smooth muscle contraction. PAF has been demonstrated to produce many of the important clinical manifestations of anaphylaxis, including decreased myocardial contractile force, coronary vasoconstriction, pulmonary edema, and a prolonged increase in total pulmonary resistance with a decrease in dynamic compliance. Indeed, blockade of PAF with experimental antagonists leads to improved cardiac function, suggesting that PAF may be involved in the late cardiac dysfunction and lethality associated with anaphylaxis. Histamine is an essential mediator in immediate hypersensitivity and inflammation, and infusion of histamine has been shown to produce the majority of the clinical features of anaphylaxis syndrome.
vomiting. Vasodilation can lead to flushing, headaches, reduced peripheral vascular resistance, hypotension, and syncpe. Contraction of smooth muscle can lead to bronchospasm, abdominal cramping, or diarrhea. Pulmonary vessel vasoconstriction can lead to pulmonary hypertension, pulmonary edema, and decreased cardiac filling pressures. Coronary vasoconstriction can lead to myocardial ischemia and decreased myocardial contractile force. Changes in atrial chronotropy and ventricular and atrial isotropy can lead to cardiac dysrhythmias. In addition to the direct actions on the target tissues, these preformed mediators, lipid-derived mediators, and cytokines activate a number of inflammatory pathways, including the complement system, clotting and clot lysis systems, and the kallikrein-kinin (contact) system, to contribute to the clinical manifestations of allergy and anaphylaxis.

Cardiovascular collapse in anaphylaxis has classically been described as a result of peripheral vasodilation, enhanced vascular permeability, leakage of plasma, and intravascular volume depletion (the “empty vessel” syndrome). However, hemodynamic reports for humans experiencing anaphylactic shock indicate that the explanation may be more complicated. In a variety of clinical settings, hypotension in anaphylaxis has been associated with an initial increase in cardiac index, which may become depressed, and altered peripheral and pulmonary vascular resistance (increased/decreased). In the setting of decreased cardiac index and elevated peripheral vascular resistance, organ perfusion is compromised, resulting in metabolic acidosis. The use of pressors alone in this situation may not improve hemodynamics as peripheral blood vessels are already maximally vasoconstricted. Aggressive volume expansion with crystalloid (or colloid) is needed in this scenario.

Pathologic features identified at autopsy in fatal cases of anaphylaxis are most commonly observed in the respiratory and cardiac systems. These include orolaryngeal edema, pulmonary hyperinflation, peribronchial vascular congestion, intra-alveolar hemorrhage, pulmonary edema, increased tracheobronchial secretions, and eosinophil infiltration of the bronchial walls. Death from asphyxia is usually caused by angioedema of the epiglottis, larynx, hypopharynx, and, to some extent, the trachea. Patients who die of vascular collapse show varying degrees of myocardial damage, visceral congestion, and other findings suggestive of a loss of intravascular blood volume. Other autopsy findings include urticarial eruptions, angioedema, visceral congestion, submucosal edema, and hemorrhagic gastritis. Notably, autopsy findings may also be normal after an anaphylactic death. A summary of the physiologic effects and clinical signs and symptoms is given in Table 117-1.

**ETIOLOGY**

Numerous agents are known to cause anaphylaxis in humans. They are organized by immunopathogenetic mechanism: IgE mediated, immune complex mediated, nonimmunologic activators, or AA modulators (Box 117-3). Reactions without identifiable causative agents are classified as physically induced or iatrogenic anaphylaxis (IA).

### Immunoglobulin E–Mediated Agents

This diverse group of agents includes foods, antibiotics, latex, drugs, and Hymenoptera stings.

#### Foods

Foods are the major identifiable causative agents, accounting for approximately one third of the cases of anaphylaxis. A variety of foods ranging from the well-known, such as nuts, shellfish, and eggs, to the obscure, such as chamomile tea (which may have cross-reactivity with ragweed), have been identified. Cow’s milk, egg, peanut, soy, wheat, fish, shellfish, and tree nuts are foods that most commonly cause anaphylaxis. Even for a person with a known history of food allergy, it may be difficult to avoid foods that may cause allergic reactions because their identity may be obscured in processing (e.g., wine contaminated with Hymenoptera venom). Because allergic foods are first absorbed transmucosally, symptoms of food anaphylaxis may first appear localized to the upper airway of the respiratory tract. When anaphylactic allergies are administered parenterally, symptoms of anaphylaxis tend to be more cardiovascular and systemic. Allergic reactions to foodstuffs are more common in children, ranging from 0.3 to 7.5%. Therapeutic and prophylactic use of large quantities of antibiotics is common in the production of beef cattle, swine, fish, poultry, and sometimes vegetables and fruits. Along with antibiotics, sodium and potassium bisulfites and metabisulfites are used as preservatives in foods. Sulfites have been used as antioxidants in the food and restaurant industry to prevent discoloration of vegetables (e.g., salad bars and avocado dips), fruits, and potatoes and to preserve fruit and vegetable juices. They are also used to prevent bacterial contamination and oxidation of wines, beers, and distilled beverages. Sensitivity to ingested sulfites has been well documented, especially among the asthmatic population. Establishing a particular foodstuff or preservative as the causative agent of anaphylaxis can be difficult.

#### Antibiotics

Benzylpenicillin, semisynthetic penicillin, and cephalosporins are the most commonly used antibiotics, with penicillin perhaps the most commonly reported medication allergy. The first penicillin-induced anaphylactic fatality was reported in 1949. Because of their low molecular weights, these antimicrobials do not themselves possess antigenic properties. Immunologically, they are haptens, simple chemicals that are not antigenic in themselves but become antigenic after the chemicals or their metabolites form a stable bond with the host proteins. Certain binding properties of particular drugs make them more likely to induce sensitization. Although patients often report a history of penicillin allergy, this usually does not stand up to close scrutiny. Studies have shown that up to 9 of 10 individuals with a reported history of penicillin allergy can safely use penicillin; these individuals usually are either mislabeled as penicillin allergic or lose their allergy after years of avoidance. Depending on the studies, the frequency of allergic reactions to penicillin varies from 0.01% to 0.05% of administrations of penicillin (1 to 5 reactions per 10,000), with an anaphylactic reaction rate less than 0.01% and a fatality rate less than 0.002% (less than 1 fatality per 50,000 penicillin administrations). Parenterally administered penicillin is responsible for most of the anaphylactic reactions. The extensive use of this drug in unsuspected sources such as foods, in which it is used as a bacteriostatic agent, may make it difficult to ascertain historically that penicillin is not the causative agent.

Cephalosporins share the β-lactam ring structure and side chains of the penicillins and have been incriminated for allergic cross-sensitivity in 1 to 8% of patients. It is unclear which steps in the processing of foods contribute to the clinical manifestations of allergy and anaphylaxis. The extent of cross-reactivity varies with the specific food and drug, ranging from 0.05% to more than 75% for certain foods and drugs. Some foods and drugs are more likely to cause allergic reactions than others. Some consumers are allergic to cephalosporins as well as to cephalosporins, but others are not. It is also not clear whether cephalosporins cause anaphylaxis in patients who have been allergic to penicillin.

#### Skin Tests

Although skin testing is commonly used to detect allergy to food, its usefulness decreases with the development of sensitization. Negative skin tests do not rule out an allergic reaction. Anaphylaxis due to ingestion of foods is usually not associated with cutaneous symptoms, and the skin tests may therefore be negative even when the patient has a history of ingestion allergy. While skin tests are negative in approximately 30% of food allergies, the specificity of these tests is unknown. False-negative results can result from incomplete sensitization or from temporary suppression of reactivity. Skin testing is the most objective method of determining the specific allergenic agent involved in a food allergy.

ECG, electrocardiographic.
Although it may be prudent to administer a class of antibiotics other than the cephalosporins when a well-documented significant history of penicillin allergy is obtained, if no other antibiotic choices are available, the first dose of cephalosporin can be administered orally under medical supervision and observation.\(^{29}\)

**Latex**

Allergy to natural rubber latex in gloves and other medical products has become a health issue for health care providers, patients, and rubber industry workers.\(^{29}\) Latex is derived from the commercial rubber tree *Hevea brasiliensis*, which is native to the southern Amazon and harvested commercially from plantations in Southeast Asia and Africa. The functional unit is a rubber particle coated with a layer of proteins, lipids, and phospholipids to provide structural integrity. Latex allergy refers to sensitivity to either the proteins or the chemical products contained in the latex products. The sensitivity reaction can be delayed (type IV) contact dermatitis or an immediate hypersensitivity (type I) reaction (asthma, urticaria, and anaphylaxis). Although latex allergy is common, affecting 0.7 to 1.1% of the population, only 220 people per year are estimated to be at risk for an anaphylactic reaction from latex.\(^{5}\)

The most common symptoms of latex allergy include allergic urticaria, rhinitis, conjunctivitis, and occupational asthma. There is evidence that patients with specific food allergies are predisposed to latex allergy.\(^{31}\) The true risks of latex-induced anaphylaxis are not known, but in a review of anaphylactic incidents in 50 children, 27% were due to latex allergy.\(^{32}\) Diagnostic tests include serologic assays and skin prick testing. There is no effective prophylaxis for latex allergy. In fact, routine use of the H\(_2\) blocker ranitidine for gastroesophageal reflux was reported to increase the risk of a heart conduction block in a case of anaphylaxis caused by latex.\(^{33}\) Avoidance of latex-containing products is the recommended approach.

**Insect Stings**

Hymenoptera venoms and fire ant stings are responsible for significant anaphylactic morbidity and mortality.\(^{14}\) The first recorded fatality from anaphylaxis was probably the hieroglyphic-documented death of King Menes of Egypt in 2641 BCE, when he succumbed to the sting of a wasp or hornet. Stinging Hymenoptera insects affect up to 13.6 million Americans annually (circa 1999), accounting for approximately 50 to 100 deaths annually.\(^5\) Allergic sensitization to Hymenoptera has been reported in 0.4 to 4% of the general population. The principal offenders (in decreasing order of frequency) are yellow jackets, honeybees, wasps, and yellow and bald-faced hornets. The imported fire ant has become a significant pest responsible for anaphylaxis, spreading from the Atlantic and Gulf coasts inland.\(^{35}\) The introduction of killer (Africanized) bees in Brazil and their subsequent northern migration make them a significant cause of sting-induced anaphylaxis in areas of Texas, Arizona, and the southwestern United States.\(^{36}\)

The Hymenoptera venoms are complex mixtures of pharmacologically and biochemically active substances. Honeybee venom has been subjected to the greatest amount of research and contains two major enzymes—hyaluronidase and phospholipase A (PLA)—and other peptides, including a mast cell-degranulating peptide. Yellow jacket venom contains not only phospholipases A and B and hyaluronidase but also kinins. Hornet venom has, in addition, acetylcholine. Wasp venom has not been extensively studied. Fire ant venom is mostly a nonproteinaceous alkaloid suspension containing PLA and hyaluronidase.

**Other Therapeutic Agents**

Heterologous sera that were used in diphtheria and tetanus equine antitoxins in the past can act as whole antigenic markers. In fact, until the advent of penicillin, these two therapeutic agents were the most commoniatrogenic causes of
anaphylaxis in humans. The use of human antisera was associated with a marked reduction in the incidence of serum-induced anaphylactic reactions. In fact, no adverse reactions were noted on repeated immunization using human tetanus antisera in approximately 250 patients who had previous anaphylactic reactions to equine tetanus antitoxins.37 Equine antisera are still used in the administration of antilymphocyte serum and in the management of venomous snake bites. Although anaphylactic reactions are rare (1:500,000), the equine antiserum should still be diluted and pretested.

Since the development of heterologous insulin hormone therapy for the management of diabetes mellitus, local and systemic allergic complications have been recognized. A large percentage of local reactions were eliminated with the introduction of purified, single-peak pork insulin. With the introduction of Humulin, an insulin preparation prepared from recombinant DNA, the incidence of anaphylaxis and insulin resistance has declined dramatically.

Allergen extracts are used diagnostically in skin testing and therapeutically in immunotherapy (also known as hyposensitization or desensitization).38 Exposure to therapeutic pollens, by injection or inhalation, can result in local allergic or systemic anaphylactic reactions. High-dose therapy, too frequent administration, or inadvertent intravascular injection increases the risk of anaphylaxis with immunotherapy.

Although corticosteroids are used in the management of acute allergic syndromes and anaphylaxis, adverse reactions to these medications have been observed after parenteral administration.39 Skin testing may demonstrate the specific class of steroids responsible for hypersensitivity, and substitution of a different class should be considered.

Local anesthetics occasionally produce adverse reactions.40 Most of these reactions are not allergic in nature but are related to a direct effect of the medication. True allergic reactions are rare and are most commonly seen with local anesthetics from the ester family (e.g., procaine, tetracaine, and benzocaine). Allergic reactions to local anesthetics belong to the amide family (e.g., lidocaine, bupivacaine, mepivacaine, and dibucaine) are extremely rare if they occur at all. Multidose vials of lidocaine contain the preservative methylparaben, which belongs structurally to the ester family. This preservative has been implicated in allergic reactions in patients with a history of previous lidocaine hypersensitivity.41 Pure lidocaine (without the methylparaben preservative) should be used intravenously (as in Bier’s block).

Anaphylactic reactions have occurred after the administration of egg embryo-grown vaccines, including the combined measles, mumps, and rubella (MMR), yellow fever, and influenza vaccines. A patient who is able to tolerate eggs orally, even if he or she has previously experienced anaphylaxis and shows a positive skin test to eggs, is likely to tolerate the vaccines. Anaphylactic reactions have also occurred against ethylene oxide (ETO), which is used to sterilize hemodialyzers. ETO can bind with human proteins such as human serum albumin (HSA), thus rendering the ETO-HSA complex allergenic.

**Immune Complex–Mediated Agents**

Anaphylactic-type reactions are uncommon complications after the administration of whole blood and immunoglobulins. The fixation of antibodies to formed elements such as red blood cells, platelets, and leukocytes and soluble components activates the complement system. This is particularly relevant in IgA-deficient patients exposed to multiple transfusions, who may have produced antibodies to IgA present in previous transfusions. With subsequent transfusions, an antigen (IgA)–anti-IgA antibody (IgG) immune complex forms, and subsequent activation of the complement cascade may occur.

**Nonimmunologic Activators**

Many of the opioid analgesics can cause anaphylactic reaction through a direct histamine release mechanism, although there is evidence that, rarely, some reactions are true IgE-mediated reactions. It is unclear how much cross-sensitivity is present among these agents.42

Radiocontrast media (RCM) represents one important class of drugs that can cause an anaphylactic reaction.1011 RCM is available as high-osmolar RCM (HRCM, >1400 mOsm/kg), iso-osmolar RCM (same as serum, 290 mOsm/kg), and low-osmolar RCM (LRCM, 500–900 mOsm/kg). In addition, depending on the charge of the iodine molecule used, RCM is classified as ionic or nonionic. The majority of RCM is ionic HRCM or nonionic LRCM.

Approximately 10 million radiologic studies using RCM are performed in the United States annually, most of which use nonionic LRCM. Of these studies, approximately 35 per 100,000 exposed patients have a serious reaction, with an estimated fatality rate of 1 to 3.9 per 1 million injections.9 The older hyperosmolar agents can cause a reaction in up to 5.6% of patients and fatalities in up to 0.01%.43 Subsequent studies put the risk of a serious reaction to high-osmolar contrast media at 0.22%, with 11.7 fatalities per 1 million injections.44 Protocols have been developed to minimize risks of a serious allergic reaction in patients who have had a previous adverse reaction to RCM but who still require additional radiographic studies with contrast. One common protocol is shown in Box 117-4.

Anaphylactic reactions to RCM are largely idiosyncratic, occur within minutes of infusion, and are independent of the dose. Risk factors for an anaphylactic reaction include a previous adverse reaction to RCM, a history of atopy or allergic disease, asthma, and certain medications. Of note, it is a misconception that a history of allergy to fish or shellfish is a contraindication to the use of RCM or increases the risk of an adverse reaction to RCM.45

The pathophysiology of anaphylactic reactions to RCM is unknown, but it is believed to be nonimmunologic. Suggested mechanisms include direct histamine release, alternative complement pathway activation, and activation of the contact system.

**Modulators of Arachidonic Acid Metabolism**

 Interruption of AA metabolism by aspirin (ASA) and other nonsteroidal anti-inflammatory drugs (NSAIDs) has been

---

**Box 117-4**

**A STANDARD TREATMENT PROTOCOL FOR PATIENTS WITH A HISTORY OF RADIOCONTRAST-INDUCED ANAPHYLAXIS**

- Prednisone, 50 mg by mouth given 13, 7, and 1 hour before the procedure.
- Diphenhydramine, 50 mg intramuscularly given 1 hour before the procedure.
- Consider ephedrine, 25 mg by mouth given 1 hour before the procedure.
- Consider an H2 antagonist, such as ranitidine, 300 mg by mouth given 3 hours before the procedure.

postulated as the mechanism responsible for anaphylactoid reactions resulting from these agents, although AA modulation, anaphylatoxin generation, and direct histamine release may all be partially responsible.\textsuperscript{46} The incidence of anaphylactoid reactions to aspirin and NSAIDs varies widely, depending on the population (healthy, atopic, or those with nasal polyps). One study estimates the incidence as 2.1 anaphylactoid reactions per 100,000 exposed patients.\textsuperscript{9} Aspirin allergy refers to a clinical spectrum ranging from ASA GI intolerance to ASA-induced asthma exacerbation, which is a true ASA-anaphylactoid reaction. Desensitization protocols have been suggested for cardiovascular patients with a history of aspirin allergy.\textsuperscript{47}

For ASA-induced cutaneous disease, an ASA desensitization protocol that can be used for cardiovascular patients in the ED is to administer ASA every 15 minutes, starting with 0.1 mg, up to 325 mg at 135 minutes.\textsuperscript{48} ASA should be avoided in patients with true anaphylactic reaction to ASA. For noncardiovascular applications, most aspirin-sensitive patients can tolerate sodium salicylate or acetyaminophen as an aspirin substitute. Of note, one of many food additives, tartrazine (foods, drugs, and cosmetics [FD&C] yellow dye number 5), is a stable azo coloring agent present in thousands of foods and drugs in the United States.\textsuperscript{49} The exact mechanism of tartrazine sensitivity is unknown, although modulation of AA metabolism and several other theories have been proposed.

### Physically Induced Anaphylaxis

Thermomechanical and physical factors (heat and cold), especially exercise, have increasingly been recognized as etiologic agents in certain anaphylactoid-like incidents.\textsuperscript{30} The mechanism is unclear, but release of mast cell and basophil mediators has been implicated. Patients with exercise-induced anaphylaxis are generally dedicated athletes who may have a personal or family atopic history. Exercise-induced anaphylaxis has been demonstrated in some cases to depend on previous ingestion of food to which the patient may be subclinically sensitive. Provocative foods, if identified, should be avoided. Patients should discontinue exercise when they experience pruritus. When exercise is continued beyond this point, clinical deterioration is likely in susceptible individuals. Prophylactic treatment with an antihistamine as a single agent or in combination with other agents may be helpful. Avoidance of precipitating factors, modification of exercise, and use of a self-injectable epinephrine kit have been recommended for patients with exercise-induced anaphylaxis.

### Idiopathic Anaphylaxis

Prednisone-responsive IA refers to an anaphylactic condition in which no eliciting factors can be detected.\textsuperscript{11,35} In the United States, it is estimated that 20,000 to 47,000 patients annually see allergists for signs and symptoms of IA. A specific causative agent cannot be found historically. Laboratory studies including a complete blood count with differential leukocyte count, erythrocyte sedimentation rate, blood chemistries, complement levels, C1 esterase inhibitor levels, serum and urinary histamine levels, urinalysis, skin testing, and occasionally more specialized tests when clinically indicated are all nondiagnostic. Food diaries and efforts to find systemic disease are often fruitless. Although IA may be life-threatening, it is usually responsive to conventional therapies, including antihistamines, sympathomimetics, and especially prednisone.\textsuperscript{36} Some cases of IA may be caused by kissing or conversion disorders.\textsuperscript{32} The overall prognosis for IA is good, but certain patients may experience recurrent IA despite intensive prophylactic administration of antihistamines, sympathomimetics, or steroids. Sometimes, IA can represent “progesterone” anaphylaxis. Women suffering from this disorder may present with recurrent episodes of anaphylaxis that are temporally related to the menstrual cycle. Other patients may have anaphylactic reactions to injection of medroxyprogesterone or luteinizing hormone-releasing hormone.

### CLINICAL FEATURES

Anaphylaxis in humans primarily affects organs that are rich in mast cells—the cutaneous, upper and lower respiratory, cardiovascular, neurologic, and gastrointestinal systems. Anaphylactic reactions range from mild to fatal with variable durations of attack. The clinical expression depends on the degree of hypersensitivity; the quantity, route, and rate of antigen exposure; the pattern of mediator release; and the target organ sensitivity and responsiveness. One cardinal feature of a serious anaphylactic reaction is its rapid onset. Most anaphylactic reactions become clinically evident within minutes (average 5 to 30 minutes) after a parenteral exposure; onset can be slower (average 2 hours) after ingestion. Most fatalities occur within the first 30 minutes after antigenic exposure. Symptoms can sometimes resolve and recur hours later in what has been termed biphasic anaphylaxis.\textsuperscript{53} In general, the sooner the clinical syndrome is manifest after antigenic exposure, the more severe the reaction. Anaphylactic reactions after parenteral antigenic exposure are usually more immediate in onset, progress more rapidly, and are more severe in quality than those occurring after topical or oral exposures. Fatal cases of anaphylaxis are usually caused by cardiovascular collapse or respiratory failure. Although urticaria and angioedema are the most common presenting symptoms in anaphylaxis (88%), fatal anaphylaxis syndromes with laryngeal edema and circulatory collapse can occur even in the absence of any premonitory warning symptoms or signs or cutaneous manifestations.

The first clinical manifestation of anaphylaxis usually involves the skin; the patient experiences generalized warmth and tingling of the face, mouth, upper chest, palms, soles, or the site of antigenic exposure. Pruritus is a nearly universal feature and may be accompanied by generalized flushing and urticaria. Patients presenting with angioedema may complain of swelling and a sensation of burning under the skin but no itchy rash. This may be followed by mild to severe respiratory distress. The patient may describe a cough; a sense of chest tightness, dyspnea, and wheeze from bronchospasm; or throat tightness, dyspnea, odynophagia, or hoarseness associated with laryngeal edema or oropharyngeal angioedema. Hypotension or dysrhythmias may manifest as light-headedness or syncope. Seizure activity caused by decreased cerebral perfusion may rarely be observed. Any of these clinical patterns may occur independently or in association with nasal congestion and sneezing; ocular itching and tearing; cramping abdominal pain; pelvic pain and uterine cramping; headache; or a sense of impending doom.

The physical examination may reveal tachypnea, tachycardia, and hypotension. Laryngeal stridor, hypersalivation, hoarseness, and angioedema indicate upper airway obstruction, whereas coughing, wheezing, rhonchi, and diminished air flow suggest lower respiratory tract bronchoconstriction. Tachycardia and hypotension suggest cardiac insufficiency. Commonly observed dysrhythmias include sinus tachycardia, premature atrial and ventricular contractions, nodal rhythm, and atrial fibrillation. Other electrocardiographic changes include nonspecific and ischemic ST-T wave changes, right ventricular strain, and intraventricular conduction defects. The patient may have a depressed level of consciousness due
to hypotension; rarely, this may be caused by a postictal state due to seizure activity. Urticaria, angioedema, rhinitis, and conjunctivitis may be evident. A summary of the observed clinical manifestations of anaphylaxis along with their related pathophysiology is presented in Table 117-1.

### Diagnostic Strategies

A good history and physical examination, coupled with a high index of suspicion, are the best diagnostic tools in approaching patients with possible anaphylaxis. A new set of clinical parameters has been advanced to aid in the clinical diagnosis of an anaphylactic reaction. The diagnosis of anaphylaxis is considered to be “highly likely” when patients present with cutaneous symptoms (itchy urticaria, flushing, and swollen lips, tongue, and throat) and either respiratory difficulty (dyspnea, wheezing, and stridor) or reduced blood pressure or symptoms of end-organ dysfunction (see Box 117-1). Anaphylaxis can be confirmed by testing for allergen-specific IgE and serum tryptase—tests that are not normally available in the ED. As clinically indicated, other diagnostic modalities may be employed concurrently to rule out other emergencies. The initial screening studies can include a complete blood count, complete metabolic panel (hypoglycemia), coagulation panel (prothrombin time, partial thromboplastin time, and international normalized ratio), cardiac enzymes, an electrocardiogram to rule out an acute coronary syndrome, urine analysis, erythrocyte sedimentation rate, and a portable chest radiograph. Serum level of serotonin and urinary 5-hydroxyindole acetic acid, catecholamines, and vanillylmandelic acid are useful to rule out carcinoid syndrome. Serum and urinary histamine and serum tryptase levels are helpful to confirm the diagnosis of anaphylaxis after the fact. The optimal time to obtain the serum histamine level is within 1 hour and serum tryptase within 1 or 2 hours (but no longer than 6 hours) of the onset of symptoms. Samples of vomitus may be collected for the allergist to create a custom radioallergosorbent test panel for later desensitization therapy. Serial arterial blood gases may help monitor clinical response. Blood culture, urine culture, computed tomography of the head and lateral soft tissue of the neck, and indirect and direct laryngoscopy can be considered depending on clinical suspicion.

### Differential Considerations

The diagnosis of an anaphylactic reaction depends largely on recognizing the key symptoms and signs (see Box 117-1) that occur abruptly after an exposure to a suspected inciting agent. Considerations for other diseases with overlapping presentations should include those shown in Table 117-2.

#### Flush Syndromes and Rash

Flushing disorders range from the benign, such as alcohol-induced flushing, to the more pathologic, such as mastocytosis or carcinoid syndrome. Scombroidosis refers to histamine poisoning from the ingestion of fish improperly stored at an elevated temperature. Histamine and cis-urocacid acid are produced by various bacteria that multiply in the spoiled fish. Patients usually present with a frightening flush but no urticaria, palpitations, syncope, nausea, vomiting, or diarrhea.

#### Stridor

In the absence of oropharyngeal angioedema or other clinical manifestations of anaphylaxis, the diagnosis of laryngeal edema should be confirmed by direct or indirect laryngoscopy to exclude epiglottitis and supraglottitis, retropharyngeal or peritonsillar abscess, laryngeal spasm, foreign body aspiration, or tumor.

### Bronchospasm

Obstructive lung diseases such as acute asthma and status asthmaticus are usually not associated with other symptoms and signs of anaphylaxis. Patients with acute pulmonary embolism may present with shock, respiratory distress, and bronchospasm. Exercise-induced anaphylaxis should be differentiated from exercise-induced asthma because the former is usually accompanied by pruritus and other systemic manifestations.

### Syncope

Vasovagal syncope is the most common differential diagnosis in the patient arriving with collapse as a result of parenteral administration of an antigen. Classically, the patient has bradycardia, hypotension, and pallor as opposed to the tachycardia, hypotension, and diaphoresis usually associated with anaphylaxis. The absence of any other clinical manifestations of anaphylaxis, along with history of stress, pain, and previous episodes of simple faints, helps point toward the diagnosis of vasovagal syncope. Other causes of syncope, such as seizure, stroke, hypoglycemia, acute coronary syndrome, or cardiac dysrhythmia, also need to be considered. Ordinary allergic reactions and especially anaphylaxis can precipitate an acute coronary syndrome.

### Shock

Clinically, anaphylactic, septic, and spinal shock may appear similarly with signs and symptoms of shock including end-organ hypoperfusion and vasodilation. Skin is usually moist and warm, suggesting a state of decreased peripheral vascular resistance. Cardiogenic, restrictive, hypovolemic, or hemorrhagic shock would more likely be seen with cold, clammy skin, suggesting a state of heightened peripheral vascular resistance. Because anaphylactic shock can progress to cardiogenic shock, measurement of central venous pressures (CVPs) may be necessary.

### Management

#### Out-of-Hospital

When a susceptible patient is reexposed to an antigen to which there has been a previous reaction, 50 mg of oral diphenhydramine should be taken if available. At the first signs of any clinical manifestations of anaphylaxis, the patient should self-administer epinephrine if available (adult dose, 0.3 mL of 1:1000 intramuscular; pediatric dose, 0.01 mL/kg of 1:1000 intramuscular). Susceptible patients may even use aerosolized epi- nephrine from a metered-dose inhaler to counteract the effects of laryngeal edema, bronchoconstriction, and other manifestations of anaphylaxis.

Multiple inhalations (e.g., 10–20 doses, resulting in the inhalation of 1.5–3 mg of epinephrine) produce therapeutic plasma levels, with the advantages of ease of administration, rapid absorption, and locally high epinephrine levels in the upper and lower airways. Epi- nephrine must be used with caution in elderly people and in those with a history of cardiac or hypertensive problems.

Out-of-hospital personnel may be required to resuscitate a moribund patient using basic life support. Their first priority should be to establish and maintain ventilation, intravenous access, cardiac monitoring, and administration of supplemental

Oxygen to keep the oxygen saturation level greater than 90%.

Local measures to decrease antigen absorption from an extremity include dependent positioning of the extremity, ice to vasoconstrict locally, and application of a loose tourniquet to obstruct the venous and lymphatic circulation. The tourniquet should be released for 1 of every 10 minutes. If an insect stinger remains, the wound should not be squeezed because it may inject more venom into the patient. The stinger should be removed gently with instruments, avoiding disturbance of the venom apparatus.

**Emergency Department**

Since most of the morbidity and mortality associated with anaphylaxis originates from acute respiratory failure or cardiovascular collapse, the immediate goal in the ED is to stabilize any cardiorespiratory insufficiencies while confirming the diagnosis of anaphylaxis and anaphylactic shock along with other diagnostic alternatives. Box 117-5 summarizes the treatment options for acute anaphylaxis.

Epinephrine and antihistamines (H1 and H2) should be administered early in most cases. Patients should have supplemental oxygen administered, large-bore (e.g., 16-gauge) intravenous lines inserted to infuse crystalloid or colloid solutions, and continuous cardiac monitoring. A large volume of crystalloid fluid may be required to reverse the hypotension associated with anaphylaxis.

Upper airway obstruction from laryngeal edema or angioedema can progress rapidly. While preparing for more definitive airway management, a chin lift or jaw thrust may help obtain a patent airway. Suctioning the oropharynx of excess
1. Immediate general interventions
   (a) Remove any triggering agent
   (b) Place patient in the Trendelenburg position if hypotensive
   (c) Assessment of airway patency, breathing, and circulation
      (i) Hyperextension of neck, jaw thrust, chin lift
      (ii) Administer supplemental oxygen by nasal cannula or non-rebreather mask
      (iii) Racemic epinephrine 0.5 mL of 2.25% in 2.5 mL of NS by nebulizer while awaiting definitive airway management
   (iv) Establish airway
      (1) Endotracheal intubation with or without RSI (rapid sequence intubation)
      (2) Adjunct airway technique (jet ventilation, LMA, surgical airway) as per local institution
   (v) Establish large-bore IVs
      (1) Administer colloid/crystalloid, titrate to blood pressure
   (vi) Pulse oximetry
   (vii) Cardiac monitoring/ECG
   (viii) Portable CXR
   (ix) Blood draw
   (x) Place a loose tourniquet proximal to the reaction site; if reaction site on extremity, place extremity in dependent position
   (xi) Inject 0.1–0.2 mL 1:1000 epinephrine locally to the reaction site

2. Specific measures
   (a) Epinephrine
      (i) Intramuscular (subcutaneous route acceptable) 1:1000
         (1) Adult: 0.3–0.5 mL every 5 min as necessary, titrated to effects
         (2) Pediatric: 0.01 mL/kg, every 5 min as necessary, titrated to effects
         (3) Alternatively, epinephrine (EpiPen) (0.3 mL) or EpiPen Jr (0.15 mL) can be administered into anterolateral thigh. Removal of clothing is unnecessary
      (ii) Intravenous 1:100,000 (0.1 mL of 1:1000 in 10 mL of NS)
         (1) Continuous hemodynamic monitoring required
         (2) 10 mL of 1:100,000 over 10 min, titrated to effects, repeat as necessary
   (b) Antihistamines
      (i) Diphenhydramine: intravenous (or oral)
         (1) Adult: 50 mg, up to 400 mg/24 hr, titrated to effects
         (2) Pediatric: 1 mg/kg, up to 300 mg/24 hr, titrated to effects
      (ii) Ranitidine: intravenous (or oral)
         (1) Adult: 50 mg IV (150 mg oral)
         (2) Pediatric: 1 mg/kg IV or oral
   (c) Aerosolized beta-agonists and others
      (i) Adult
         (1) Albuterol: 2.5 mg, diluted to 3 mL of NS, may be given continuously
         (2) Levalbuterol: 0.625–1.25 mg, diluted to 3 mL of NS, may be given continuously
         (3) Ipratropium: 0.5 mg in 3 mL of NS, repeat as necessary
      (ii) Pediatric
         (1) Albuterol: 2.5 mg, diluted to 3 mL of NS, may be given continuously
         (2) Levalbuterol: 0.31–0.625 mg, diluted to 3 mL of NS, may be given continuously
         (3) Ipratropium: 0.25 mg in 3 mL of NS, repeat as necessary
   (d) Methylprednisolone
      (i) Adult: 125–250 mg IV
      (ii) Pediatric: 1–2 mg/kg/IV

3. Special situations
   (a) Refractory hypotension
      (i) Glucagon: 1–5 mg IV over 5 min, followed by 5–15 µg/min continuous infusion
      (ii) Consider:
         (1) Discontinue epinephrine
         (2) Dopamine, 5–20 µg/kg/min continuous infusion and/or dobutamine 5–20 µg/kg/min continuous infusion
         (3) Norepinephrine: 8–12 µg/min (2–3 mL/min; 4 mg added to 1000 mL of D5W provides a concentration of 4 µg/mL)
   (b) Patients on beta-blockade
      (i) Glucagon: 1–5 mg IV over 5 min, followed by 5–15 µg/min continuous infusion
      (ii) Transcutaneous pacing for bradycardia
      (iii) Atropine for bradycardia
         (1) Adult: 0.3–0.5 mg IV/subcutaneous, to a maximum of 3 mg
         (2) Pediatric: 0.02 mg/kg IV/subcutaneous, to a maximum of 2 mg
      (iv) Isoproterenol: 0.05–0.2 µg/kg/min (1–2 mg in 500 mL of D5W, infused at a rate of 0.5–2 mL/min)
   (c) Refractory bronchospasm
      (i) Aminophylline: 5.6 mg/kg loading dose IV over 20 min, followed by 0.1–1.1 mg/kg/hr continuous infusion
      (d) Hypertensive crisis due to unopposed alpha-blockade
      (i) Nitroprusside: 0.3–10 µg/kg/min (6 µg/kg/min, neonates) continuous infusion
      (ii) Phentolamine: 5–20 mg IV
   (e) Dysrhythmia
      (i) Lidocaine 1–2 mg/kg IV bolus, followed by 2 mg/min continuous infusion

CXR, chest x-ray; D5W, 5% dextrose in water; ECG, electrocardiogram; LMA, laryngeal mask airway; NS, normal saline.

secretions may be necessary. A nasopharyngeal or oropharyngeal airway may aid in maintaining a patent airway at this stage. Racemic epinephrine, delivered as a 2.25% solution (0.5 mL placed in a nebulizer in 2.5 mL of normal saline), may be used as a temporizing measure. A laryngeal airway mask, jet ventilation, or surgical airway may be needed for difficult airways.

The success rate of intubation is improved when it is performed early and before soft tissue swelling progresses. Oral endotracheal intubation is the route of choice because
significant anatomic distortion may be present as a result of edema. Sedation and paralysis should be used with caution because a distorted airway may preclude intubation after paralysis. Patients in acute respiratory distress should be given definitive airway treatment without waiting for results of an arterial blood gas. Once a patent airway has been obtained and supplemental oxygen delivered, therapy should focus on relieving the patient’s bronchospasm.

**Epinephrine**

Drugs used in the treatment of anaphylaxis either inhibit the release of chemical mediators or reverse the effects of mediators on target tissues. Epinephrine, with its combined alpha-and beta-adrenergic agonist actions, is the first drug of choice in the treatment of anaphylaxis. The alpha-agonist effects of epinephrine increase peripheral vascular resistance and reverse peripheral vasodilation, vascular permeability, and systemic hypotension. The beta-agonist effects of epinephrine produce bronchodilation, cause positive inotropic and chronotropic cardiac activity, and result in increased production of intracellular cyclic adenosine monophosphate (cAMP). Epinephrine therefore reverses bronchospasm, stimulates increased cardiac output, and inhibits further mediator release. The alpha- and beta-agonist actions of epinephrine can also be potentially dangerous. Excessive alpha-agonist activity can result in a hypertensive crisis. Excessive beta-agonist activity can increase myocardial oxygen consumption through increased wall tension, contractility, and chronotropism and can result in myocardial ischemia or infarction. Increased automaticity and chronotropism can produce hemodynamically significant supraventricular and ventricular tachydysrhythmia. Epinephrine should be used with caution in elders and those with known coronary artery disease and should be avoided in patients with life-threatening tachydysrhythmias.

The route of epinephrine administration depends on the severity of the clinical presentation. Subcutaneous epinephrine is usually effective in situations in which the clinical manifestations are mild and the patient is normotensive. In the patient with diffuse, generalized urticaria, subcutaneous absorption of epinephrine may be slow and unpredictable and the intramuscular route may be more efficacious.

For subcutaneous and intramuscular injections, the initial dose of epinephrine is 0.01 mL/kg of a 1:1000 solution to a maximum of 0.5 mL of a 1:1000 solution (0.5 mg). A fraction of the total dose (0.1 or 0.2 mL) should be administered at the site of antigenic exposure if accessible (e.g., a bee sting or antigen injection in an extremity).

If the patient demonstrates severe upper airway obstruction, acute respiratory failure, or shock (systolic blood pressure <80 mm Hg, not associated with a ventricular tachydysrhythmia), intravenous epinephrine should be administered. Use of the intravenous route with epinephrine increases the risk of supraventricular, accelerated idioventricular, and ventricular tachydysrhythmia; accelerated hypertension; and myocardial ischemia, including the stunned heart syndrome. Because of these risks, dilution and slow administration are recommended. The initial intravenous dose should be 10 mL of a 1:100,000 dilution of aqueous epinephrine over 10 minutes. This is equivalent to a 100-μg bolus administered at 10 μg/min for 10 minutes. If no improvement is seen, a continuous infusion should be set up. Mixing 1 mL of a 1:1000 dilution of epinephrine in 250 mL of 5% dextrose in water (D5W) results in a concentration of 4 μg/mL. This can be started at 1 μg/min and increased to 4 μg/min if needed. In children and infants, an infusion rate of 0.1 μg/kg/min is advised, increasing in increments of 0.1 μg/kg/min to a maximum of 1.5 μg/kg/min.

Continuous cardiac monitoring should be done at all times. If a percutaneous intravenous line cannot be established, alternative routes are available. In addition to the subcutaneous and intramuscular routes of administration, intraosseous or sublingual injection or endotracheal nebulization should be considered. The dosage and concentration guidelines for these routes of administration of epinephrine are the same as those for intravenous administration.

**Antihistamines**

In addition to epinephrine, antihistamines should be used in all cases of anaphylaxis, although their role in severe or persistent cases is limited. The antihistamines competitively block the action of circulating histamines at target tissue cell receptors but have no role in decreasing mediator release and have no effect on the leukotrienes. There are seven classes of H1 antihistamines, and members of the ethanalamine family, such as diphenhydramine hydrochloride, and the alkylamine family, such as chlorpheniramine maleate, are potent H1 antagonists. Diphenhydramine hydrochloride is the most commonly used H1 antihistamine. The typical dose is 50 mg every 4 to 6 hours in adults or 5 mg/kg/day in divided doses for the pediatric population. Diphenhydramine hydrochloride orally or by intramuscular injection may be the only medication required for mild to moderate reactions. A loading dose of 1 to 2 mg/kg intravenously (IV) to a maximum of 100 mg is recommended for severe reactions, although too large a dose or too rapid administration can result in marked sedation and hypotension. Chlorpheniramine can be administered to children by the same routes at a standard dose of 10 to 20 mg or 0.35 mg/kg/day in divided doses.

Blockade of H2 receptors may be beneficial with simultaneous H1 antihistamine therapy. H2 antagonists may inhibit the effect of histamine on myocardial and peripheral vascular tissue. Ranitidine (50 mg IV) or other H2 blockers should be considered, followed by an oral course as an outpatient.

**Aerosolized Beta-Agonists**

Bronchospasm refractory to epinephrine may respond to a nebulized beta-agonist such as albuterol sulfate (Ventolin and Proventil), levalbuterol (Xopenex), terbutaline (Brethaire and Brethine), bitolterol (Tornalate), pirbuterol (Maxair), and/or metaproterenol (Alupent 5%). Continuous nebulization of the beta-agonists may be necessary for persistent bronchospasm. The use of anticholinergic therapy with ipratropium bromide (Atrovent) is an additional option in the management of acute bronchospasm. Anticholinergic medications decrease cyclic guanosine monophosphate levels, thereby decreasing mediator release and reversing the action of mediators on target tissue cells. Nebulized ipratropium bromide is used in a dose of 0.5 mg (2.5 mL of a 0.02% solution).

As a second-line therapy for refractory bronchospasm, an aminophylline bolus (5.6 mg/kg loading dose IV over 20 minutes), followed by a maintenance infusion (0.1–1.1 mg/kg/hr), can also be added. Aminophylline is an old drug with a narrow therapeutic window. Its main purported action is bronchodilation, although it may also act to potentiate the action of catecholamines. Side effects include atrial fibrillation, nausea, vomiting, and abdominal pain.

**Corticosteroids**

Systemic corticosteroids have an onset of action of approximately 4 to 6 hours after administration and therefore are of limited benefit in the acute treatment of the anaphylactic
patient. They are most useful in persistent bronchospasm or hypotension and have some theoretical benefits in the prevention of the biphasic reaction. Rare cases of deterioration after corticosteroid administration may be the result of anaphylactic sensitivity to this medication. An initial intravenous loading dose of hydrocortisone (Solu-Cortef), 250 mg to 1 g, or methylprednisolone (Solu-Medrol), 125 to 250 mg, followed by oral prednisone over 7 to 10 days is an acceptable regimen after the anaphylactic episode.

Vasopressors

In patients with persistent hypotension despite administration of epinephrine and large volumes of intravenous crystalloid, the use of colloid solutions (e.g., 5% albumin) should be considered in addition to crystalloid because of increased vascular permeability in anaphylaxis. If the CVP is less than 12 mm Hg, crystalloid and colloid fluids should be administered first. If the CVP is greater than 12 mm Hg, dopamine (5 µg/kg/min) should be started and titrated to effect. Dobutamine can be added if myocardial depression is judged to be an important cause of the hypotension. Other causes of elevated filling pressures other than vascular volume or myocardial dysfunction should be considered (e.g., vasopressor administration, increased intrapulmonary and intrathoracic pressures, vasoconstriction, or pulmonary artery hypertension). If the cause of hemodynamic instability is uncertain, a pulmonary artery catheter to monitor wedge pressure and cardiac output may be required to guide the administration of fluid and vasopressor. If pulmonary hypertension exists, hyperventilation, hyperoxegenation, and large doses of steroids should be considered. The use of true pressors with primarily alpha-adrenergic activity, such as norepinephrine, could be considered if all of these measures fail to restore the inadequate hemodynamics.

In the rare case in which the anaphylactic patient develops a hypertensive crisis secondary to unopposed alpha- or beta-adrenergic activity from the treatment, nitroprusside drips or phentolamine should be considered. Dysrhythmias from elevated circulating catecholamines can be treated with lidocaine.

Patients Receiving Beta-Blockade

Glucagon, with positive inotropic and chronotropic cardiac effects mediated independently of alpha- and beta-receptors, may be helpful in patients who are receiving beta-blockers and who do not respond to epinephrine and antihistamines. Glucagon is thought to effect positive inotropism by augmenting cAMP synthesis through a nonadrenergic pathway. The initial dose is 1 mg for adults and 0.5 mg for children subcutaneously, intramuscularly, or intravenously, and the patient may require a glucagon infusion of 1 to 5 mg/hr to sustain its therapeutic effect. Side effects include nausea, vomiting, hypokalemia, and hyperglycemia. Atropine (0.3–0.5 mg IV) and isoproterenol (0.05–0.2 µg/kg/min; 1–2 mg in 500 mL of D5W, infused at a rate of 0.5–2 mL/min) can be tried as second-line therapy. Atropine is probably more useful for bradycardia. Isoproterenol should be used as the last resort for the rare patient who is in refractory shock after all the preceding therapy.

DISPOSITION

Most patients with anaphylaxis respond to early aggressive management and can be safely discharged home. Patients with mild to moderate anaphylaxis who respond completely to initial treatment are appropriate for discharge after an observation period of 2 to 6 hours. An oral antihistamine, such as diphenhydramine hydrochloride 25 to 50 mg every 6 hours for 48 hours, may prevent possible relapse. These patients should be instructed to return to the ED if their symptoms recur. They should be warned about the sedating side effects of the antihistamines. Oral H2 blockers for 48 hours may be useful, and patients with initially persistent bronchospasm or hypotension who required initial steroid therapy should continue oral prednisone for 7 to 10 days. Patients with initially persistent bronchospasm should continue a metered-dose beta-adrenergic bronchodilator inhalant (e.g., albuterol [Ventolin] and metaproterenol [Alupent]). Hospital admission should be considered for patients who have experienced hypotension, upper airway involvement, prolonged bronchospasm, or other indications of a severe reaction. Although the risk of clinical deterioration after apparently complete resolution of a severe anaphylactic reaction is minimal, symptoms redevelop in a small proportion of patients 24 to 48 hours after the initial systemic reaction. This may be related to the high-molecular-weight neutrophil chemotactic factor-mediated late-phase reaction of the biphasic allergic response, which peaks in 4 to 12 hours and lasts up to 48 hours. Patients taking chronic beta-blocker medications may be susceptible to a similar rebound after the initial therapeutic interventions resolve. These patients may be candidates for an extended observation.

Prevention

Spending a few additional minutes with the patient before discharge, obtaining an allergy history, offering environmental modifications, and educating the patient on initiating treatment for recurrence may decrease morbidity and mortality associated with subsequent episodes of anaphylaxis (Box 117-6). Avoid prescribing medications with marginal benefits...

BOX 117-6 PREVENTION OF ANAPHYLAXIS AND ANAPHYLACTIC DEATH

1. Get thorough drug allergy and atopic history.
2. Check all drugs for proper labeling.
4. Give drug in distal extremity if possible when parenteral route necessary.
5. Always have resuscitation equipment available when administering antigentic compounds.
6. Ensure that patients wait in emergency department 30 minutes after drug administration.
7. Use unrelated drugs when feasible in susceptible population.
8. When antiserum is essential, use human if available.
9. If heterologous serum is essential, always perform pretest.
10. Predisposed patients should carry warning identification (Medic-Alert, wallet identification).
11. Predisposed patients are taught self-injection of epinephrine, and patients are instructed to carry treatment kit at all times.
12. Patients should avoid known antigens (stinging insects, foods, antibiotics).
13. Perform skin test and consider hyposensitization immunotherapy when appropriate (see section on stinging insect anaphylaxis).
14. Pretreat with antihistamines, steroids if appropriate (see section on radiocontrast media reactions).
for patients at high risk of significant allergy and allergic reaction. A thorough personal and family drug allergy and atopic history can be useful before starting a new drug therapy. All drugs should be correctly identified before being administered. Whenever possible, the oral route of administration is preferred to the parental route to decrease the severity of a systemic anaphylactic reaction.

Physicians who administer antigenic compounds in their medical practice must be prepared to manage an anaphylactic reaction, and resuscitation equipment should be readily available. Because most anaphylactic reactions that follow parenteral administration begin within 30 minutes, patients should be observed during this period, discharged only if completely asymptomatic, and given a warning to return if there are subsequent symptoms.

Human antiserum is now available for rabies, tetanus, and diphtheria; however, heterologous equine antiser is still used (e.g., for snake bites). Intradermal pretesting should be performed before treatment if time permits, as outlined in the product monographs. However, even pretesting solution can precipitate an anaphylactic reaction. Furthermore, unnecessary pretesting sensitizes predisposed patients to future hypersensitivity reactions to antiserum.

Predisposed patients who have experienced a moderate or severe anaphylactic reaction should be taught self-administration of an oral antihistamine (e.g., diphenhydramine) on known exposure and self-injection of epinephrine (e.g., EpiPen and Ana-Kit) at the first indication of allergic symptoms or signs. Epinephrine injection kits have a limited shelf life, which is prolonged by refrigeration. Although the true effectiveness of these kits is unknown, they should be readily available at all times, with one kit available at home, one at work or school, one in the patient’s purse or briefcase, and one in the patient’s automobile. Predisposed patients should be strongly encouraged to carry warning identification stating their hypersensitivity (Medic-Alert bracelet or wallet card).

Pretreatment with antihistamines and steroids significantly decreases the frequency and severity of anaphylactoid reactions in patients who have had prior adverse reactions to RCM. Skin testing and hyposensitization immunotherapy by an allergist are an appropriate way to minimize the frequency and severity of subsequent anaphylactic reactions from bee stings in an appropriately sensitive population. Patients with an uncertain history of penicillin allergy should be referred for additional testing to confirm the allergy.

**URTICARIA AND ANGIOEDEMA**

Urticaria and angioedema are physical findings with a multitude of causes. Urticaria (hives) is a reaction that consists of papules or wheals that are nonpitting, edematous, pruritic, slightly erythematous, raised circular or annular, and range in size from millimeters to several centimeters (Fig. 117-4). The centers of the wheals are usually clear and the borders can be serpiginous. The erythema is due to dilation of blood vessels in the dermal layer of the skin, and the edematous wheals are due to transudation from these blood vessels. Urticaria favors the extremities and trunk and is usually transient, with crops of hives appearing and resolving spontaneously in a matter of hours.

Angioedema is pathogenetically similar to urticaria but involves the deeper dermal and subcutaneous tissue. The presence of urticaria usually indicates a mast cell component to the reaction. Conversely, the absence of urticaria or pruritis suggests that the reaction is kinin related. Angioedema commonly involves the face, mouth, lips, tongue, extremities, and genitalia. Recurrent episodes of angioedema and urticaria that last less than 6 weeks are considered acute (90%), and those that persist longer than 6 weeks are classified as chronic (10%). Acute urticaria tends to be associated with angioedema in approximately half of cases. In approximately 40% of cases, urticaria is present alone, without angioedema. In the remaining 10%, angioedema is present exclusively without urticaria. Angioedema without urticaria could be the presenting physical finding of C1 inhibitor deficiency, or these cases may be angiotensin-converting enzyme (ACE) inhibitor induced.

It should be remembered that urticaria and angioedema are merely presenting symptoms and signs of potentially distinct underlying disease entities. Most mast cell-related attacks of acute urticaria and angioedema are hypersensitivity and IgE-mediated allergic reactions (similar to anaphylaxis). A variety of chemical allergens (e.g., foods, drugs, RCM, and Hymenoptera venoms) and physical stimuli (e.g., dermatographism, heat, wet, cold, vibratory, exercise, and solar) may also be present with angioedema and associated urticaria and pruritis.

Angioedema without urticaria and pruritis is usually kinin related and causes include hereditary angioedema (HAE), acquired C1 inhibitor deficiency (ACID), and ACE inhibitors. All three result in elevated bradykinin levels. In the case of HAE and ACID, the deficiency of C1 inhibitor causes activation of the kallikrein-kinin system, with consumption of kininogen, and results in increased production of bradykinin. In the case of ACE inhibitor drugs, the inhibition of ACE, one of the main inactivators of bradykinin, results in increased bradykinin levels. Substance P is also thought to play a role in ACE inhibitor-associated angioedema.

HAE affects less than 200,000 people in the United States and may account for 15,000 to 30,000 ED visits annually. It is an autosomal dominant condition caused by C1 esterase inhibitor deficiency or functional deficiency, which is biochemically confirmed by low levels of C4 and C1 esterase inhibitor activity. This ultimately results in intermittent elevated bradykinin levels, resulting in angioedema. The cardinal symptoms and signs of HAE include edema of the airway, face, genitalia, or extremities and abdominal pain associated with nausea, vomiting, and diarrhea. These clinical manifestations may occur singly or in combination. Trauma and stress are common precipitating factors. There is usually a family history.
ACID is clinically indistinguishable from HAE attacks and is often associated with underlying lymphoproliferative diseases. The underlying disease results in consumption of C1 inhibitor or the development of anti-C1 inhibitor autoantibodies. It is less common than HAE, typically involves older patients, and there is an absence of family history.

ACE inhibitor-induced angioedema has an incidence of 0.1% to 0.7% and has a predilection for the tongue, lips, and laryngeal soft tissue. The highest incidence occurs in the first month of therapy, but it can occur as many as 10 years after therapy is started. Increased risk factors include African American race, smoking, older age, and female gender. Diabetes decreases the risk. The pathophysiology is thought to be prevention of the metabolism of bradykinin and substance P, both of which are potent mediators of tissue inflammation. Most patients who develop angioedema on ACE inhibitors should be able to tolerate angiotensin receptor blocker drugs.

The clinical evaluation of angioedema starts with a focused search for emergency conditions, followed by a detailed history aimed at identifying the underlying cause. Life-threatening airway compromise can occur if the angioedema involves the upper airway. HAE, ACID, ACE inhibitors, thermal burn, or local allergic reaction to inhaled drugs (e.g., Quincke’s disease) tend to cause glossopharyngeal angioedema, resulting in upper airway obstruction, dysphagia, or both. The detailed history is aimed at eliciting exposures to foods, drugs, physical stimuli, infection (especially viral hepatitis), occupational elements, and insect stings. The differential diagnosis includes evolving anaphylaxis syndrome, erythema multiforme minor, bullous pemphigoid and dermatitis herpetiformis, urticarial vasculitis, mastocytosis, HAE (C1 esterase deficiency), ACID, ACE inhibitor-associated angioedema, and serum sickness, among others. The constellation of pruritus, urticarial rash or angioedema, hypotension, and wheezing after exercise should raise the possibility of exercise-induced anaphylaxis. Angioedema of the upper extremity raises the possibility of superior vena cava syndrome. Brawny edema and shock raise the possibility of capillary leak syndrome.

Management of acute urticaria and angioedema (mast cell related) in the ED is first focused on stabilizing respiratory insufficiency and hemodynamic instability. Antihistamines (both H1 and H2) are the first-line therapeutic drugs. Epinephrine can be considered for moderate to severe cases but should be used with caution in patients older than 35 years to minimize the risk of precipitating an acute coronary syndrome. Steroids may help in preventing recurrence. In the longer term, the most effective treatment of urticaria and angioedema involves removal of the etiologic factors. H1 antihistamines such as diphenhydramine (12.5–100 mg per dose every 4 hours) or the nonsedating agents such as cetirizine, loratadine, or fexofenadine are the first-line drugs. Hydroxyzine (10–100 mg daily at bedtime) can be tried when other H1 antihistamines are inadequate. Because 85% of histamine receptors in the skin are H1 and 15% H2, adding an H2 blocker (e.g., ranitidine or cimetidine) theoretically would benefit a histamine-induced urticarial reaction. Doxepin (25–100 mg/day) is an excellent alternative because it has both H1 and H2 activity. Topical steroids are of no value, and systemic steroids should be reserved for pressure urticaria, vasculitis urticaria, and intractable chronic urticaria.

Management of angioedema without urticaria (kinin related) is somewhat more problematic with fewer therapeutic options. Life-threatening acute attacks of kinin-related angioedema do not usually respond satisfactorily to treatment with epinephrine, antihistamines, or steroids. Active airway management is the mainstay of treatment. Aerosolized racemic epinephrine may help stabilize the airway edema. For HAE, fresh frozen plasma (FFP), which contains C1 inhibitor, has been reported to be effective in abolishing acute attacks; however, there are rare reports of FFP exacerbating the angioedema. Steroids should be avoided if the patient is known to have HAE.

Although not approved by the Food and Drug Administration, four agents are either being used in other countries or under investigation for the treatment of HAE. The use of C1 inhibitor replacement protein (C1-INHPRP), a product of pooled human plasma, has become the standard of care for the treatment of HAE in Europe, Canada, Japan, and Argentina. A recombinant C1-INHPRP has been developed and is in phase II/III trials in the United States for the treatment of HAE. Both products have been shown to shorten time to relief of symptoms, but the recombinant product has a shorter half-life.

Another investigational agent in phase II/III trials is ecallantide-DX88. It is a kallikrein inhibitor and prevents the generation of bradykinin. The fourth investigational agent with two completed phase III studies is Icatibant. It is a bradykinin receptor-2 antagonist. Both of these agents have been shown to shorten time to relief of symptoms for HAE. At the time of this writing, recombinant C1-INHPRP still is not approved by the FDA for the treatment of HAE. Pooled C1-INHPRP was approved by the FDA in October 2008 for the prevention of HAE but not for the treatment of acute attacks. Ecallantide-DX 88 has completed phase II/II trials. It currently carries the orphan drug designation for the treatment of angioedema and fast track designation for the treatment of acute HAE. Icatibant currently carries the orphan drug status designation for the treatment of HAE.

For ACE inhibitor-induced angioedema, the treatment is mainly supportive. There is a report of FFP being used with success in a severe case of ACE inhibitor-induced angioedema. It is thought that the benefit may have been due to the effect of kininase II in breaking down accumulated bradykinin. Theoretically, since there is impaired breakdown of bradykinin in ACE inhibitor-induced angioedema, perhaps the bradykinin receptor blocker class of drug may ultimately also be found to be effective in shortening time to relief of symptoms.

### Mastocytosis

Mastocytosis refers to disorders caused by too many mast cells in the body. There are two forms of mastocytosis. Cutaneous mastocytosis, also called urticaria pigmentosa, occurs when the mast cell hyperplasia is in the skin. Cutaneous mastocytosis is more common and affects mostly children. Systemic mastocytosis refers to the clinical syndrome caused by mast cell hyperplasia in bone marrow, gut mucosa, liver, or spleen. Pathologic fractures, osteoblastic lesions on skeletal radiographs, cutaneous pigmented lesions, abdominal pain, diarrhea, hepatosplenomegaly, lymphadenopathy, headache, flushing, anemia, and, rarely, vascular collapse (from released vasoactive substances) are some of the clinical findings in this form of mastocytosis. The diagnosis is made by a 24-hour urine collection for histamine or its metabolites, PGD2, or serum tryptase level. Adjunct diagnostic measures include bone scans, skeletal surveys, or upper gastrointestinal workup (upper gastrointestinal series, small bowel radiograph, computed tomography scan, and endoscopy). A skin or bone marrow biopsy helps confirm the diagnosis. Treatment options include steroids, interferon-α, H1 antihistamines for pruritus and flushing (aspirin can be added if flushing is severe), H12 blockers for dyspepsia, and tricyclics for headache.
| Allergy and allergic diseases are caused by overreactions of the immune system. Anaphylaxis is a systemic, life-threatening allergic reaction, precipitated within minutes of an exposure to an allergen in a previously sensitized individual. Diagnostic features include a history of recent exposure, urticaria, angioedema, flush, respiratory difficulty, dizziness, syncope, hypotension, and GI symptoms. Foods, drugs, insect stings, and latex are the main identifiable etiologic agents. |
| Priority should be given to airway management and stabilizing any hemodynamic instability. Epinephrine is the first drug of choice for the management of anaphylaxis. Prolonged treatment with epinephrine or glucagon may be required for patients receiving beta-adrenergic blockade. Both H₁ and H₂ antihistamines should be used in all cases of anaphylaxis. Fluid, vasopressors, and inotropic agents should be instituted for refractory hypotension, guided by CVP or pulmonary catheter. Corticosteroids should be given in severe anaphylactic reactions or to prevent the biphasic anaphylaxis. |
| Hospitalization or prolonged observation should be considered for patients who have experienced hypotension, upper airway involvement, prolonged bronchospasm, or other indications of a severe reaction. |
| Identifying and avoiding the causative agent, prescribing abortive medications (EpiPen kits), and referral to an allergist are most important in long-term management and prevention of anaphylaxis and should be discussed by the emergency physician with the patient and family before the patient’s discharge. |
| The clinical evaluation of urticaria and angioedema starts with airway assessment, followed by a detailed history aimed at identifying the underlying cause. Life-threatening airway compromise can occur if the angioedema involves the upper airway. |
| Angioedema is clinically a single disease entity, but the underlying causes can be distinctly different, requiring different treatment plans. If the angioedema is IgE mediated (usually urticaria is present), antihistamines (both H₁ and H₂) are the first-line therapeutic drugs. Epinephrine can be considered for moderate to severe cases. If the angioedema is kinin mediated (usually urticaria is absent), treatment is mostly supportive. FFP has been used with varying success in HAE, ACID, and ACE-induced angioedema. New drugs are being evaluated for this form of angioedema. |
**Perspective**

Skin conditions and related complaints account for an estimated 4 to 12% of all emergency department (ED) visits. In addition to medical and family history, three factors are particularly important: onset and evolution of the skin problem, associated symptoms, and prior treatment. Cutaneous eruptions can be manifestations of primary dermatologic disease or can signal underlying systemic illness.

For physical examination, the patient must be undressed and adequate lighting must be present. The scalp, mouth, and nails should be thoroughly examined. Although the examination depends largely on inspection of the skin, palpation helps assess the texture, consistency, and tenderness of the lesions.

Skin lesions may be divided into growths and rashes. Growth subdivisions include epidermal, pigmented, and dermal or subcutaneous proliferative processes. Rashes may be divided into two groups depending on whether the epidermis is involved. Lesions and rashes with epidermal involvement include eczematous rashes; scaling; and vesicular, papular, pustular, and hypopigmented rashes. Rashes without epidermal involvement include erythema, purpura, and induration.

The diagnosis is aided by the configuration of the lesions and distribution on the body’s surface. Occasionally, a configuration is specific for a disease; however, the morphology of the primary lesion is usually given more diagnostic weight. Finally, many skin diseases have preferential areas of involvement, so the location of the eruption may aid in diagnosis.

**Scales, Plaques, and Patches**

**Fungal Infection**

**Principles of Disease**

The dermatophytooses are superficial fungal infections that are limited to the skin. A variety of lesions may occur, but the most common are scaling, erythematous papules, plaques, and patches, which often have a serpiginous or wormlike border. Dermatophytes generally grow best in excessive heat and moisture and grow only in the keratin or outer layer of the skin, nails, and hair. Keratin tends to accumulate in body folds, such as between toes and in the inguinal area, the axilla, and the inframammary areas. With the exception of tinea capitis, dermatophyte infections are not markedly contagious.

Any eruption thought to be a dermatophyte infection can be examined under the microscope in a potassium hydroxide (KOH) preparation. The specimen is examined for the characteristic branching hyphae of the dermatophytes or the short, thick hyphae and clustered spores of tinea versicolor. Affected hair, nail, or scales may be cultured using Sabouraud agar incubated at room temperature for 2 or 3 weeks.

**Tinea Capitis**

**Clinical Features.** Tinea capitis is a fungal infection of the scalp. Although primarily regarded as a disease of preschool children, tinea capitis is becoming increasingly recognized in adults, infants, and neonates. It is more common among African Americans, although the reasons for this are unknown.

The current epidemic in the United States caused by *Trichophyton tonsurans* differs from the epidemic of the 1940s and 1950s caused by *Microsporum audouinii* in that many patients have seborrheic-like scaling in the absence of alopecia. Clinically, “black dots,” representing hair broken off near the scalp, may be noted. Hair loss occurs because hyphae grow within the shaft, rendering it fragile, so that the hair strands break off 1 to 2 mm above the scalp. Circular patches of partial baldness may result. The disease may be transmitted by close child-to-child contact and contact with household pets, hats, combs, barber’s shears, and similar items. Complications include lymphadenitis, bacterial pyoderma, tinea corporis, pigmented pityriasis alba, “id” reaction after treatment, secondary bacterial infection, and scarring alopecia.

**Differential Considerations.** The differential diagnosis of tinea capitis includes alopecia areata, atopic dermatitis, nummular eczema, bacterial infection, psoriasis, seborrheic dermatitis, “tinea” amiantacea, trichotillomania (hair pulling), and Langherans cell histiocytosis.

**Diagnostic Strategies.** A KOH preparation is not helpful in the presence of a kerion or the absence of alopecia, in which case a fungal culture should be obtained. A bacterial culture should be considered in the case of kerion to exclude superinfection. A toothbrush, Papanicolaou smear cytology brush, or moistened cotton swab is helpful for obtaining quick, painless sampling of large areas of the scalp.

**Management.** Systemic therapy is required for tinea capitis. Treatment usually begins with griseofulvin 20 mg/kg/day taken as a single dose with a fat-containing food for a minimum of 6 weeks, or 2 weeks after clinical resolution of inflammation. Patients should be referred for monthly follow-up.
Table 118-1 Definitions of Skin Lesions

<table>
<thead>
<tr>
<th>LESION</th>
<th>APPEARANCE</th>
</tr>
</thead>
<tbody>
<tr>
<td>Macule</td>
<td>Flat; color differs from surrounding skin</td>
</tr>
<tr>
<td>Patch</td>
<td>A macule with surface changes (i.e., scale or wrinkling)</td>
</tr>
<tr>
<td>Papule</td>
<td>Elevated skin lesion &lt;0.5 cm in diameter</td>
</tr>
<tr>
<td>Plaque</td>
<td>Elevated skin lesion &gt;0.5 cm in diameter; without substantial depth</td>
</tr>
<tr>
<td>Nodule</td>
<td>Elevated skin lesion &gt;0.5 cm in diameter and depth</td>
</tr>
<tr>
<td>Cyst</td>
<td>Nodule filled with expressible material</td>
</tr>
<tr>
<td>Vesicle</td>
<td>Blister &lt;0.5 cm in diameter filled with clear fluid</td>
</tr>
<tr>
<td>Bullae</td>
<td>Blister &gt;0.5 cm in diameter filled with clear fluid</td>
</tr>
<tr>
<td>Pustule</td>
<td>Vesicle filled with cloudy or purulent fluid</td>
</tr>
<tr>
<td>Crust</td>
<td>Liquid debris that has dried on the skin surface; usually moist and yellowish brown</td>
</tr>
<tr>
<td>Scale</td>
<td>Visibly thickened stratum corneum; usually white</td>
</tr>
<tr>
<td>Lichenification</td>
<td>Epidermal thickening characterized by visible and palpable skin thickening and accentuated skin markings</td>
</tr>
<tr>
<td>Induration</td>
<td>Dermal thickening that feels thick and firm</td>
</tr>
<tr>
<td>Wheal</td>
<td>Papule or plaque of dermal edema; often with central pallor and irregular borders</td>
</tr>
<tr>
<td>Erythema</td>
<td>Red appearance of skin caused by vasodilation of dermal blood vessels; blanchable</td>
</tr>
<tr>
<td>Purpura</td>
<td>Red appearance of skin caused by blood extravasated from disrupted dermal blood vessels; nonblanchable</td>
</tr>
<tr>
<td>Macular purpura</td>
<td>Flat, nonpalpable</td>
</tr>
<tr>
<td>Papular purpura</td>
<td>Elevated, palpable</td>
</tr>

</table>

Evaluation. Higher dosages may be needed. Alternative therapy includes fluconazole 200 mg/day (adults) or 3 to 5 mg/kg/day (children), itraconazole 200 mg daily (adults) and 3 to 5 mg/kg/day (children) for 4 to 6 weeks, oral terbinafine at 3 to 6 mg/kg/day for 4 to 6 weeks, or terbinafine cream once a day for 8 weeks. Selenium sulfide shampoo 250 mg twice weekly decreases shedding of spores.

Kerion

A kerion is a dermatophytic infection, usually of the scalp, that appears as an indurated, boggy inflammatory plaque studded with pustules. It is commonly confused with bacterial infections. Kerions should be treated as tinea capitis, with the addition of prednisone 1 mg/kg/day for 1 or 2 weeks to help decrease the inflammatory reaction and subsequent scarring. If bacterial superinfection exists, oral cephalaxin or dicloxacillin can be added for the first week of treatment.

Tinea Corporis

Clinical Features. Tinea corporis is the classic “ringworm” infection. It affects the arms, legs, and trunk and is classically a sharply margined, annular lesion with raised or vesicular margins and central clearing (Fig. 118-1). Lesions may be single or multiple, the latter occasionally being concentric. Tinea cruris, which involves the groin, is similar in appearance and may also include the perineum, thighs, and buttocks, but the scrotum is characteristically spared.

Differential Considerations. The differential diagnosis of tinea cruris includes granuloma annular psoriasis, intertrigo with secondary candidiasis, and erythrasma.

Management. Infections of the body, groin, and extremities usually respond to topical measures alone. A number of effective topical antifungal agents are available, including clotrimazole (Lotrimin), haloprogin (Halotex), miconazole (Micatin), tolnaftate (Tinactin), terbinafine, naftifine, and griseofulvin 1%. Two or three daily applications of the cream form of any of these preparations result in healing of most superficial lesions in 1 to 3 weeks. Acute inflammatory lesions displaying oozing or blisters should be treated additionally (four times a day) with open, wet compresses of Burow’s solution—an aluminum acetate solution that is useful as a soothing wet dressing for inflammatory skin conditions. There is often involvement of the feet and toenails.

Tinea Pedis

Tinea pedis, or athlete’s foot, appears with scaling, maceration, vesiculation, and fissuring between the toes and on the plantar surface of the foot. In extensive cases, the entire sole may be involved. A secondary bacterial infection may occur. The vesicular pustular form of tinea pedis should be considered when vesicles and pustules on the instep are noted. The differential diagnosis includes contact dermatitis and dyshidrotic eczema. A KOH preparation should help differentiate between these processes. Treatment is similar to that of tinea corporis.
Tinea Versicolor

Clinical Features. Tinea versicolor is a superficial yeast infection caused by *Pityrosporum ovale.* Superficial scaling patches occur mainly on the chest and trunk but may extend to the head and limbs. As the name implies, lesions can be a variety of colors, including pink, tan, or white. The disease may be associated with pruritus, but medical care is often sought because the spots do not tan. On physical examination, a fine subtle scale is noted that may appear hypopigmented (Fig. 118-2). Pale yellow or orange fluorescence under Wood’s light is sometimes present. The differential diagnosis includes vitiligo and seborrheic dermatitis. A KOH preparation reveals short hyphae mixed with spores (“chopped spaghetti and meatballs”).

Management. Tinea versicolor is treated with 2.5% selenium sulfide shampoo, imidazole creams, or oral ketoconazole as a single 400-mg dose or 200 mg daily for 3 to 5 days. Recurrence rates vary from 15 to 50%, and recurrence is considered the rule rather than the exception. Monthly prophylaxis with propylene glycol and water, selenium shampoo, or azole creams can help prevent recurrences. Pigmentation may not return to normal for months.

Tinea Unguim

Clinical Features. Tinea unguium results in nails that are opaque, thickened, cracked, and crumbled. Subungual debris is present, and the nail may contain yellowish longitudinal streaks. The nail of the great toe is most commonly involved. Involvement of all of the nails of the hands and feet is rare.

Management. Topical therapy of the nails alone rarely results in a cure because penetration into the nail keratin is poor. Fingernails typically respond more rapidly to therapy than toenails. Oral griseofulvin and ketoconazole require prolonged courses with high relapse rates and numerous side effects. Newer agents such asitraconazole, fluconazole, and terbinafine are safer and more effective. They also offer shorter treatment periods, thus improving compliance. The infection may be resistant to this regimen as well, however, and surgical removal of the nail is occasionally required. Recurrence is common.

Candidiasis

Perspective

Infection by *Candida albicans* can occur in infancy and old age; in people with acquired immunodeficiency syndrome (AIDS), pregnancy, obesity, malnutrition, diabetes and other endocrine imbalances, and malignancy; and those with other debilitating illnesses. Patients treated with corticosteroids, immunosuppressive agents, and antibiotics are also prone to cutaneous fungal infections.

Oral Thrush

Clinical Features. Oral thrush is the most common clinical expression of *Candida* infection. Thrush is most common in newborns, with one third being affected by the first week of life. It appears as patches of white or gray friable material covering an erythematous base on the buccal mucosa, gingiva, tongue, palate, or tonsils. Fissures or crust at the corners of the mouth may be present. The differential diagnosis of oral thrush includes lichen planus, which is not easily scraped off like *C. albicans*. Oral mucous membrane infection with *C. albicans* is an AIDS-defining illness. If the patient does not use dentures and has not taken antibiotics, underlying immunosuppression should be considered.

Management. Treatment of oral thrush involves painting the mouth with 1 mL of oral nystatin suspension (100,000 U/mL) four times a day for infants or 4 to 6 mL four times a day swish and swallow for older children and adults. Treatment should be continued for 5 to 7 days after the lesions disappear. Clotrimazole troches dissolved in the mouth two to five times daily is a preferable treatment option for adults.

Patients with oral candidiasis because of dentures should soak their dentures overnight in dilute (1:10) sodium hypochlorite solution.

Cutaneous Candidiasis

Clinical Features. Cutaneous candidiasis favors the moisture and maceration of the intertriginous areas—the interdigital web spaces, groin, axilla, and intergluteal and inframammary folds. Lesions appear as moist, bright red macules rimmed with a collarette of scale, which represents the pustule roof with scalloped borders. Small satellite papules or pustules are just peripheral to the main body of the rash. These satellite lesions are the most typical indicators of a *Candida* infection. Intertriginous lesions are prone to bacterial superinfection.

Candidal onychia and paronychia are occupational conditions in those whose hands are frequently immersed in hot water. These infections also occur with thumb sucking by children who have thrush. The paronychial area becomes red and swollen and the nails thick and brittle, with transverse ridging. Destruction of the nail plate may occur.

Differential Considerations and Diagnostic Strategies. The differential diagnosis of cutaneous candidiasis includes contact dermatitis,

the removal of excessive moisture and maceration. Lesions chronic, recurrent candidiasis.

frequently to the nail folds for 6 to 8 weeks. A search for cotton liners. Nystatin or clotrimazole cream should be applied sparingly to affected areas. Prescription creams, such as econazole, ketoconazole, or sulconazole, are also effective.

Protecting the hands from water is an integral part of the treatment of candidal paronychia. Prolonged immersion should be avoided and contact with water prevented by gloves with cotton liners. Nystatin or clotrimazole cream should be applied frequently to the nail folds for 6 to 8 weeks. A search for underlying immunocompromise should begin in patients with chronic, recurrent candidiasis.

Diaper Dermatitis

Clinical Features

Diaper dermatitis is a common disorder that is exacerbated by heat, moisture, friction, and the presence of urine and fecal material. Occlusive clothing in infants tends to foster all of these. Lesions begin as erythematous plaques in the genital, perianal, gluteal, and inguinal areas. More severe involvement results in moist, eroded lesions that may extend beyond the primary areas of appearance.

Infection with *C. albicans* and fecal bacterial flora is an important contributory factor to the development of diaper dermatitis. Lesions infected with *Candida* are moist, red patches with well-demarcated borders. Papular or pustular satellite lesions are also present.

Diaper dermatitis may reflect the presence of atopic or seborrheic dermatitis in the infant. The presence of lesions elsewhere on the body—particularly on the face in cases of atopic dermatitis or the scalp in cases of seborrhea—alerts the physician to these possibilities. Ammonia and bacteriallocated enzymes produce dermatitis as contact irritants. Such rashes are accompanied by characteristic odors. The existence of diaper dermatitis as a true allergic contact dermatitis is rare.

Management

Treatment consists primarily of altering the physical environment in which diaper dermatitis thrives. Excess clothing should be removed, and occlusive plastic or rubber diaper covers should not be used. Diapers should be changed frequently and left off for prolonged periods if possible. Sterilized cloth diapers are preferred.

If exudative lesions are present, treatment with topical cool wet compresses of saline or Burow’s solution is indicated for 2 or 3 days. Continuous air exposure of the area should be attempted. Zinc oxide (Desitin) may dry the area. Severe contact or seborrheic dermatitis may require short-term treatment with topical corticosteroids, such as 1% hydrocortisone in a cream base. Ointment-based topical medications for treatment of diaper dermatitis should be avoided because their occlusive nature enhances moisture retention. Nystatin cream or powder should be applied to lesions infected with *Candida*.

- SCALY PAPULES

Fungal lesions are typically scaly, as are lesions of secondary syphilis. Additional scaly diseases are discussed next.

Pityriasis Rosea

Pityriasis rosea is a mild skin eruption predominantly found in children and young adults. The lesions are multiple pink or pigmented oval papules or plaques 1 to 2 cm in diameter on the trunk and proximal extremities. Mild scaling may be present. The lesions are parallel to the ribs, forming a Christmas tree–like distribution on the trunk. Oral lesions are rare. In children, papular or vesicular variants of the disease may occur.

In half the cases, the generalized eruption is preceded by 1 week by the appearance of a “herald patch.” This is a larger lesion, 2 to 6 cm in diameter, that resembles the smaller lesions in other respects. The eruption is usually asymptomatic, although pruritus may be present.

Pityriasis rosea is self-limited, resolving in 8 to 12 weeks. Its cause is unknown, although a virus is suspected. The differential diagnosis includes tinea corporis, guttate psoriasis, lichen planus, drug eruption, and secondary syphilis. Recurrences are rare. Treatment is usually unnecessary, except for symptomatic alleviation of bothersome pruritus.

Atopic Dermatitis

Principles of Disease

Atopic dermatitis (AD) is a common dermatologic condition encountered in the ED and commonly referred to as “eczema” or “chronic dermatitis.” AD is the cutaneous manifestation of an atopic state, and although it is not an allergic disorder, it is associated with allergic diseases such as asthma and allergic rhinitis. Patients with AD are known to have abnormalities of both humoral and cell-mediated immunity. The exact mechanism is unclear, but eosinophil, mast cell, and lymphocyte activation triggered by increased production of interleukin-4 by specific T helper cells seems to be involved. Increased IgE levels are found in most but not all patients with AD, but there is a poor correlation between the severity of the dermatitis and the serum IgE level. The course of AD involves remissions and exacerbations. More than 90% of patients have the onset of AD before 5 years of age. New-onset AD in older children or adults should raise suspicion for other diagnoses.

Clinical Features

Atopic dermatitis has no pathognomonic skin lesions or unique laboratory parameters. The United Kingdom’s Working Party revised diagnostic criteria include itchy skin plus three or more of the following: history of flexural involvement, generalized dry skin, history of asthma or hay fever, onset of rash before 2 years of age, and flexural dermatitis. These criteria are quite sensitive (85%) and specific (96%).

Skin lesions generally appear as inflammatory thickened, papular, or papulovesicular lichenification and hyperpigmentation. The skin is typically dry and may be scaly, but in the acute phase, it may also be vesicular, weeping, or oozing. The distribution of lesions varies with the age of the patient. In infants, inflammatory exudative plaques are seen on the cheeks, extensor surfaces, and in the diaper area. Older children and adults have lesions in the antecubital and popliteal flexion areas, neck, face, and upper chest. Infantile AD usually
begins in the fourth to sixth month of life and improves by the third to fifth year of life. The childhood form occurs between 3 and 6 years of age and resolves spontaneously or continues into the adult form.\textsuperscript{28}

Intense pruritus is a hallmark of AD. During flares, patients may present with complaints of intense itching and failure of routine treatments to control their symptoms. Patients may also present with secondary infections. The itching may be focal or generalized, is worse during the winter, and is triggered by increased body temperature and emotional stress. It may be particularly annoying at night. Excoriations may be prominent, and secondary bacterial infection of excoriated lesions is common. Repeated scratching and rubbing produce lichenification, a condition of hyperpigmentation, thickening of the skin, and accentuation of skin furrows. Lichenification is a common feature of chronic AD.

**Differential Considerations**

The differential diagnosis of infantile AD includes histiocytosis X, Wiskott-Aldrich syndrome, chronic seborheic dermatitis, phenylketonuria, Bruton’s X-linked agammaglobulinemia, psoriasis, and scabies. Fixed-drug eruptions and contact dermatitis round out the differential diagnosis regardless of age.\textsuperscript{25,27} Complications of AD include pyogenic skin infections, otitis externa, cataracts, keratoconus, retinal detachment, and cutaneous viral infections.

**Management**

The optimal protocol for management in children has not been established. Treatment should be aimed at controlling inflammation, dryness, and itching. The use of sedating antihistamines at bedtime can be beneficial in patients with AD who have comorbid allergic conditions and sleep disturbances.

Daily skin care should be reviewed with patients or caregivers. General recommendations for all patients include avoidance of nonspecific skin irritants, wool, nonessential toiletries and detergents, and using cotton clothing as much as possible. Patients should take daily warm baths or showers for approximately 10 to 15 minutes to hydrate the skin. Baths are followed by gentle pat drying and immediate application of a topical anti-inflammatory medication on the affected areas and a moisturizer such as Cetaphil cream on the asymptomatic areas. Medium-potency topical corticosteroids may be sufficient to treat moderate flares. Ointment-based medications are usually better tolerated by most patients during an acute flare.

Skin dryness may be treated by the application of lubricating ointments such as Vaseline or 10% urea in Eucerin cream (not lotion). Treatment of exudative areas includes the application of wet dressings. Such dressings are useful for their moisturizing, anti-inflammatory, and antipruritic actions. Two or three layers of gauze soaked in Burow’s solution should be applied for 15 to 20 minutes four times a day. Antihistamines may be helpful in reducing the pruritus and are also useful for their sedative and soporific effects, although there is no convincing evidence that H\textsubscript{1} antihistamines decrease itching in patients with atopic eczema.\textsuperscript{3}

Topical corticosteroids are the cornerstone of therapy and should be prescribed in ointment form. When the dermatitis is severe, a fluorinated corticosteroid ointment such as half-strength betamethasone valerate should be applied to affected areas of the body three times a day. Fluorinated corticosteroids should not be used on the face because they can produce permanent cutaneous atrophy. Milder corticosteroid preparations such as 0.025% triamcinolone ointment may be used on the face and intertriginous areas. Patients with extremely severe disease may require systemic steroids. Ultraviolet B treatment is moderately effective, although its mechanism of action is not well understood.\textsuperscript{28}

Cyclosporine and other immunosuppressant agents are being used with some promising benefit. Further studies are needed to determine ideal dosing and safety profiles for these agents.\textsuperscript{28}

Topical calcineurin inhibitors, including tacrolimus ointment and pimecrolimus cream, are nonsteroidal topical immunosuppressants approved in the United States for use on children 2 years or older and are useful for treating lesions on the thinner skin areas (face, groin, and axillae) where repeated applications of topical corticosteroids may result in skin atrophy or striae.\textsuperscript{29} A burning sensation at the site of application may occur. Note that the Food and Drug Administration has issued a “black box” warning concerning long-term continuous treatment with topical calcineurin inhibitors and cancer, although there is currently no evidence for a causal link.\textsuperscript{30,31}

Inpatient admission should be strongly considered for patients with generalized erythema and exfoliation (erythroderma), and intractable itching as skin breakdown and severe secondary bacterial or viral skin infections may occur.

**Skin Infections in Patients with Atopic Dermatitis**

Patients with AD are susceptible to infection and colonization by a variety of organisms because of their defective skin barrier functions and local skin immunodeficiency. Widespread disseminated viral infections, such as eczema molluscatum, eczema vaccinatum, or eczema herpeticum, and recurrent staphylococcal pustulosis are especially concerning.\textsuperscript{29}

Eczema molluscatum is self-limited. Eczema vaccinatum results from exposure of patients to vaccinia virus either via intentional inoculation or via contact with someone recently immunized against smallpox. Therapy of eczema vaccinatum requires prompt administration of intravenous immunoglobulin, which can be obtained from the Centers for Disease Control and Prevention.\textsuperscript{32} Eczema herpeticum constitutes a medical emergency. Patients present with disseminated eruptions of dome-shaped vesicles that may or may not be superimposed on areas of eczematous rashes, with the head, neck, and trunk commonly affected. Fever, malaise, and local lymphadenopathy are variable depending on the timing of presentation and host characteristics. Complications include keratoconjunctivitis, viremia, multiorgan involvement with meningitis, and encephalitis.\textsuperscript{32} Clinical suspicion of eczema herpeticum mandates initiation of intravenous acyclovir in conjunction with antistaphylococcal antibiotics for possible bacterial superinfection. Lumbar puncture should not be attempted if infected lesions are present over the lumbar area. Ophthalmology consultation is needed for patients with periorcular or suspected eye involvement.

**Pustules**

**Impetigo**

**Principles of Disease**

Impetigo is a slowly evolving pustular eruption, most common in preschool children. Currently, *Staphylococcus aureus* is the most common pathogen, with group A streptococcus a distant second.\textsuperscript{31} Poor health and hygiene, malnutrition, and various antecedent dermatoses, especially atopic dermatitis, predispose individuals to impetigo.
Clinical Features

Streptococcal impetigo is found most often on the face and other exposed areas. The eruption often begins as a single pustule but develops into multiple lesions. It begins as 1- to 2-mm vesicles with erythematous margins. When these break, they leave red erosions covered with a golden yellow crust. Lesions may be pruritic but usually are not painful. Regional lymphadenopathy is commonly present. Lesions are contagious among infants and young children and less so in older children and adults. Postpyodermal acute glomerulonephritis is a recognized complication of streptococcal impetigo.

Staphylococcal impetigo may be differentiated from streptococcal impetigo (erythema) by little surrounding erythema in the staphylococcal infection that is more superficial. Other diagnostic considerations are herpes simplex virus (HSV) and inflammatory fungal infections. A Gram’s stain obtained from the weepy erosion after removing the crust will reveal gram-positive cocci.

Bullous impetigo is caused by staphylococci infected by phage group 2. This form is seen primarily in infants and young children. The initial skin lesions are thin-walled, 1- to 2-cm bullae. When these rupture, they leave a thin serous crust and collarate-like remnant of the blister roof at the rim of the crust. The face, neck, and extremities are most often affected. The differential diagnosis is contact dermatitis, HSV infection, superficial fungal infections, and pemphigus vulgaris. A Gram’s stain of the fluid from a bulla reveals gram-positive cocci. Cultures are positive in 95% of cases.

Management

Systemic and topical therapies are equally successful in treating impetigo. For more extensive lesions, systemic treatment should be used. There is no evidence, however, that systemic antibiotics prevent the development of acute glomerulonephritis. The efficacy of topical mupirocin 2% ointment three times a day and oral erythromycin, 250 mg four times a day for 10 days in adults or 30 mg/kg/day in children, or cephalaxin, 30 to 40 mg/kg/day three times for 7 to 10 days, is similar. Mupirocin should be avoided if there is concern about meticillin-resistant strains.

Therapy for bullous impetigo consists of an oral penicillinase-resistant semisynthetic penicillin such as dicloxacillin, 250 mg four times a day for 5 to 7 days for adults, or erythromycin, 250 mg four times a day in adults or 30 to 50 mg/kg/day in children. If the infection is limited to a small area, mupirocin 2% ointment three times a day may be applied. Without treatment, impetigo heals within 3 to 6 weeks.

Folliculitis

Clinical Features

Folliculitis is an inflammation in the hair follicle, usually caused by *S. aureus*. It appears as a pustule with a central hair. The lesions are usually on the buttocks and thighs, occasionally in the beard or scalp, and may cause mild discomfort. Differential diagnosis includes acne, keratosis pilaris, and fungal infection. Gram-negative folliculitis with *Pseudomonas aeruginosa* occurs with infected hot tubs and swimming pools or in individuals taking antibiotics for acne, and it can be differentiated from staphylococcal folliculitis by a Gram’s stain of the lesion.

Management

Treatment with an antiseptic cleanser such as povidone-iodine or chlorhexidine every day or every other day for several weeks is usually adequate. For patients with extensive involvement, a 10-day course of erythromycin, 250 mg four times a day, or dicloxacillin, 250 mg four times a day, may be added.

Hidradenitis Suppurativa

Hidradenitis suppurativa affects the apocrine sweat glands. Recurrent abscess formation in the axillae and groin resembles localized furunculosis. The condition tends to be recurrent and may be extremely resistant to therapy. Hidradenitis suppurativa may be treated with drainage of abscesses. Antistaphylococcal antibiotics are useful if administered early and for a prolonged period. Many cases do not respond, however, and eventually require local excision and skin grafting of the involved area. Antiandrogen therapy may be considered if antibiotics do not produce improvement.

Carbuncle

A carbuncle is a large abscess that develops in the thick, inelastic skin of the back of the neck, back, or thighs. Carbuncles produce severe pain and fever. Septicemia may accompany the lesions. The diagnosis of skin abscess, furuncle, or carbuncle is usually made clinically.

Local heat should be applied to furuncles and carbuncles, which should be incised and drained when fluctuant. Antibiotics are unnecessary with incision and drainage unless cellulitis or septicemia is present.

Community-Associated Methicillin-Resistant *Staphylococcus Aureus*

The incidence of community-associated meticillin-resistant *Staphylococcus aureus* (CA-MRSA) has soared since the first report in 1993. In many major U.S. cities, CA-MRSA is now the most common pathogen cultured from ED patients presenting with skin and soft tissue infections. Concern exists that CA-MRSA may be more virulent than meticillin-sensitive strains and colonization with CA-MRSA may produce more overt infections.

Epidemiology

Hospital-acquired MRSA isolates can survive on a variety of inanimate surfaces, sometimes for weeks. It is unclear whether this is also true for CA-MRSA isolates; if it is true, their presence on such items as clothing, towels, and athletic equipment might contribute to outbreaks. Pets (including dogs and cats), livestock, and birds have been identified as MRSA carriers; their role in MRSA transmission to humans requires further evaluation.

Clinical Features

CA-MRSA infections most often present as skin and soft tissue suppuration such as an abscess, furuncle, or cellulitis. Lesions frequently exhibit central necrosis and are often confused with spider bites by patients. No clinical features distinguish with certainty skin and soft tissue infections caused by MRSA from those caused by meticillin-susceptible *S. aureus*. Although rare, CA-MRSA infection can also present as necrotizing fasciitis. Recurrences of CA-MRSA cellulitis are common. Contagion among the close household contacts of patients, as well
as correctional facility, school, and sports-team contacts, is well recognized.

Management

Several studies have demonstrated excellent outcomes for abscesses caused by CA-MRSA that are treated with incision and drainage alone. If antibiotics are needed, information on local antibiotic-resistance patterns can help clinicians assess the likelihood of CA-MRSA infection and guide decisions regarding empirical treatment. Obtaining a specimen for culture and susceptibility testing, which was considered to be unnecessary in the pre-CA-MRSA era, may be useful in guiding therapy. Specimens are obtained at the time of incision and drainage of purulent lesions.

In patients with larger abscesses, systemic signs of infection, or both, antimicrobial therapy is needed in addition to incision and drainage. The optimal oral antimicrobial regimen for the treatment of skin and soft tissue infections is not known. The type and route of therapy should be guided by the severity of the clinical syndrome.

Clindamycin combines MRSA activity with effectiveness against the majority of other gram-positive organisms. Side effects include diarrhea, Clostridium difficile colitis, and increasing rates of clindamycin resistance. Rifampin has anti-MRSA activity, but resistance readily develops, so it should not be used alone. Its long half-life allows once-a-day administration. It penetrates well into all tissues and body fluids. It has a high potential for drug-drug interactions. Linezolid, a newer antimicrobial agent, is active against almost all CA-MRSA isolates and group A streptococci. Disadvantages of its use include high cost, lack of routine availability, hematologic side effects, and potential for resistance among S. aureus strains. Prolonged linezolid administration increases the likelihood of resistance.

Trimethoprim-sulfamethoxazole or tetracycline is not recommended as sole empirical therapy for a nonpurulent cellulitis of unknown cause because of group A streptococci resistance to these agents. A β-lactam antibiotic may augment treatment. Cephalosporins and macrolides, including newer ones, are ineffective against CA-MRSA. Fluoroquinolones should be avoided because S. aureus resistance develops readily and is already widely prevalent.

Patients with large abscesses, abscesses in high-risk locations, fever, signs of systemic infection, young age, or immunodeficiency should prompt consideration of hospitalization. The detailed management of invasive disease due to CA-MRSA is discussed elsewhere. Vancomycin is still considered the parenteral drug of choice for patients with invasive S. aureus infection, although clinical failures have been reported. It seems reasonable to combine vancomycin with another effective antistaphylococcal agent because many antibiotics have better bactericidal activity. In severely ill patients, carbapenems such as meropenem, panipenem, and ertapenem, which are active against CA-MRSA and synergistic with vancomycin, should be used. Use of parenteral clindamycin (not recommended as monotherapy), bactrim, and linezolid has been described. In addition, daptomycin and tigecycline are now approved for the treatment of skin and soft tissue infections caused by MRSA. A fixed combination of the streptogramins quinupristin and dalfopristin (Synercid) can be used to treat CA-MRSA skin and soft tissue infections. Its use has been limited by the potential for drug-drug interactions and by side effects.

Recurrent infections are generally treated like initial episodes. Some providers recommend “decolonization” strategies, although neither the indications for their use nor their effectiveness in reducing the risk of recurrences is established.

Decolonization strategies include the use of intranasal mupirocin to reduce nasal carriage of MRSA; however, eradication of nasal colonization appears to be transient. The efficacy of attempts to eradicate CA-MRSA among household members has not been studied.

Prevention

Common antiseptics appear to retain reasonable activity against CA-MRSA, although the results of recent studies are somewhat conflicting. Good personal hygiene including appropriate hand-washing techniques, separation of infected patients from other types of patients, and routine cleaning of shared equipment are essential to limiting CA-MRSA spread.

Gonococcal Dermatitis

Clinical Features

The arthritis-dermatitis syndrome is the most common presentation of disseminated gonococcal disease. It occurs in 1 or 2% of patients with gonorrhea, affecting women primarily. Fever and migratory polyarthralgias commonly accompany the skin lesions. The lesions are often multiple and have a predilection for periarticular regions of the distal extremities.

The lesions begin as erythematous or hemorrhagic papules that evolve into pustules and vesicles with an erythematous halo (Fig. 118-3). They closely resemble the lesions of meningococemia at this stage. They are tender and may have a gray necrotic or hemorrhagic center. Healing with crust formation usually occurs within 4 or 5 days, although recurrent crops of lesions may appear even after antibiotics have been started.

Diagnostic Strategies

The lesions usually have a negative culture for gonorrhea, and the Gram’s stain only occasionally reveals the organisms. A more reliable diagnostic technique is immunofluorescent antibody staining of direct smears from pustules. This method indicates that the lesions may be the result of hematogenous dissemination of nonviable gonococci.

Management

Current treatment of disseminated gonococcal infection is ceftriaxone, 1 g intramuscularly (IM) or intravenously (IV) every 24 hours, or ceftriaxime or cefotaxime, 1 g IV every 12 hours.
8 hours. Patients allergic to β-lactam antibiotics may be treated with spectinomycin 2 g IM every 12 hours. A total of 7 days of antibiotic therapy is required, with the remaining course of cefixime, 400 mg twice a day, cefuroxime or ciprofloxacin, 500 mg twice a day, or ofloxacin, 400 mg twice a day. Ciprofloxacin and ofloxacin are not recommended due to increasing resistance patterns or for pregnant women or children younger than 17 years.52,53 Hospitalization is recommended for patients in whom the diagnosis is uncertain and for those who have septic arthritis, meningitis, or endocarditis.

**ERYTHEMA**

Cellulitis is an infection of the skin tissue denoted by erythema, swelling, and local tenderness (Fig. 118-4).54-58 Erysipelas is a streptococcal infection of the skin and subcutaneous tissue. The involved area is red, indurated, and edematous.59 These disorders are discussed in Chapter 135.

**RED MACULES**

**Drug Eruption**

**Principles of Disease**

A given drug can produce a skin eruption of a different appearance in different patients or a different appearance in the same patient on different occasions. The most common eruptions are urticaria (hives) (Fig. 118-5) and, more commonly, morbilliform rashes (Fig. 118-6).

Drug reactions tend to appear within a week after the drug is taken, with the exception of reactions to semisynthetic penicillins, which commonly occur later. Skin lesions may appear after a drug has been discontinued and may worsen if the drug or its metabolites persist in the system. Special note should be made of penicillin because it is the most common cause of drug reaction. Serum sickness and urticaria are the most common manifestations of penicillin allergy. Atopic patients and those with a history of hay fever, asthma, or eczema are at special risk.

On the other hand, a number of drugs in common use rarely produce eruptions. Among these are acetaminophen, aluminum hydroxide (Maalox), codeine, digoxin, erythromycin, ferrous sulfate, meperidine (Demerol), morphine, and prednisone.

**Clinical Features**

Some of the more common skin reactions produced by commonly used drugs are listed in Table 118-2. Exanthematus drug eruptions resemble the skin manifestations of various viral or bacterial infections and are usually widespread symmetric maculopapular eruptions. Severe cases may progress to exfoliative dermatitis.

Eczematous drug rashes resemble those of contact dermatitis but are generally more extensive. They begin as erythematous or papular eruptions that may become vesicular. Prior sensitization to a topical medication is common in cases of this type of eruption.

Vasculitic lesions begin as erythematous papules or nodules but may ulcerate and become gangrenous. Urticarial vasculitis is characterized by persistent urticarial lesions with histologic evidence of leukocytoclastic vasculitis. Wheel-and-flare–like lesions that hurt or burn more than itch, lesions lasting more than 24 hours, and urticarial lesions that leave prolonged pigmentary changes or inflammatory lesions should prompt suspicion for urticarial vasculitis.60 Purpuric drug eruptions

*The most common causes of drug-induced urticaria are aspirin and penicillins.
†The long-acting sulfonamides have been linked to Stevens-Johnson syndrome.
may be the result of bone marrow suppression, platelet destruction, or vasculitis (Fig. 118-7). Ultimately, a skin biopsy is needed to confirm the diagnosis of vasculitis.

Photosensitive drug reactions require the presence of sunlight and are seen most commonly on sun-exposed areas of skin. This class of reactions is commonly divided into phototoxic and photoallergic. Phototoxic reactions are more common. Sulfonamides, sulfonylureas, thiazide diuretics, and tetracyclines are common causes (see Fig. 118-7). This type of reaction does not primarily involve immunologic mechanisms and occurs in any person taking an adequate quantity of the drug and exposed to sunlight. The lesions usually have the appearance of a severe sunburn but may be bullous or papular. Pruritus is typically minimal or absent.

Photoallergic reactions are the result of antigen formation that results in the formation of sensitized lymphocytes. These reactions therefore represent a delayed immunologic response. A photoallergic reaction occurs only in sensitized individuals, usually 2 weeks or longer after exposure to the drug and sunlight. Its occurrence is not dose related, and the eruption usually appears eczematous and intensely pruritic. Chlorpromazine, promethazine, and chlor Diazepoxide are common sensitizers of photoallergic reactions.

Patients who develop photoallergic reactions should be withdrawn from inciting drugs. Patients who are subject to photosensitive drug eruptions may be required to avoid prolonged sunlight exposure. Sunscreen containing 5% amino benzoic acid should be used during any such exposure.

Fixed-drug eruptions appear and recur at the same anatomic site after repeated exposure to the same drug. The lesions are usually sharply margined and round or oval. They may be pigmented, erythematous, or violaceous. Pruritus may be prominent.

Differential Considerations

The differential diagnosis of drug eruptions includes viral exanthem, chronic exfoliative erythroderma caused by psoriasis or atopic dermatitis, malignancy, scarlet fever, staphylococcal scarlatiniform eruptions, and Kawasaki disease.

Management

Treatment of drug eruptions should begin with discontinuation of the inciting agent. Patients should be warned that drug eruptions clear slowly after discontinuation of the offending agent. Itching may be treated with the application of a drying antipruritic lotion such as calamine. Cool compresses, tepid water baths with colloidal oatmeal (Aveeno) emollient or cornstarch, and diphenhydramine (Benadryl), 50 mg (5 mg/kg/24 hr in children) every 6 hours, are likely to be beneficial.

Staphylococcal Scalded Skin

Clinical Features

Staphylococcal scalded skin syndrome generally occurs in children 6 years of age or younger. It is caused by an infection with phage group 2 exotoxin-producing staphylococci. The illness begins with erythema and crusting around the mouth. The erythema then spreads down the body, followed by bulla formation and desquamation. Mucous membranes are usually not involved, but minimal involvement is occasionally seen. After desquamation occurs, the lesions dry up quickly, with clinical resolution in 3 to 7 days.

Management

Most group 2 toxin-producing organisms are penicillin resistant. Although most patients will recover without antibiotic treatment, IV therapy with 50 to 100 mg/kg of nafcillin daily or oral cloxacillin 50 mg/kg/day or dicloxacillin is recommended.

Toxic Epidermal Necrolysis

Principles of Disease

Many consider Stevens-Johnson syndrome (SJS) and toxic epidermal necrolysis (TEN) as a continuous spectrum of the same disease. Both are true dermatologic emergencies. The main feature of non–staphylococcal-induced TEN, or Lyell’s disease, is the separation of large sheets of epidermis from underlying dermis. Drugs, including the long-acting sulfa drugs, penicillin, aspirin, barbiturates, phenytoin, carbamazepine, allopurinol, and nonsteroidal anti-inflammatory drugs, are an important cause of TEN. TEN has occurred after vaccination and immunization against poliomyelitis, measles, smallpox, diphtheria, and tetanus. It has also been found in association with lymphoma.

Clinical Features

Toxic epidermal necrolysis commonly begins with prodromal symptoms, such as malaise, rhinitis, sore throat, body aches, and fever. These are followed by the abrupt development of a macular rash that may or may not appear as target lesions.

Mucous membrane involvement commonly precedes the rash in TEN. The macular exanthem usually starts centrally and then spreads to the extremities. The exanthem becomes confluent and dermal-epidermal dissociation ensues, resulting in a positive Nikolsky’s sign, denudation with shear stress, and the skin is commonly painful to the touch.

Mucous membrane involvement becomes more apparent during the progression phase. Involvement of the conjunctivae and cornea may lead to permanent scarring and blindness. The full thickness of epidermis is involved. The two conditions are easily histologically distinguishable with a skin biopsy (Fig. 118-8). A mortality rate of 15 to 20% is expected with this condition.

Management

The treatment of TEN includes discontinuation of the offending agent, fluid replacement, and aggressive infection control.
The mainstay of treatment is excellent supportive care, prevention of secondary infection, and expert wound management. This is usually best accomplished in a center with burn expertise.

**Toxic Shock Syndrome**

**Principles of Disease**

Toxic shock syndrome (TSS) is an acute febrile illness characterized by a diffuse desquamating erythroderma. Classically composed of high fever, hypotension, constitutional symptoms, multiorgan involvement, and rash, the syndrome gained notoriety in the early 1980s because of association with tampon use. However, it is also well-known in men and children. Its appearance has often been linked to exotoxin-producing *S. aureus*. Most cases of nonmenstrual TSS occur in the postoperative setting. TSS has also been associated with various staphylococcal and streptococcal infections, including empyema, osteomyelitis, fasciitis, septic abortion, peritonsillar abscess, sinusitis, burns, and subcutaneous abscess.

TSS is associated with severe group A beta-hemolytic streptococcal infections. It has been reported in previously healthy patients, immunocompromised patients, and elderly patients. Fatigue, localized pain, and nonspecific symptoms herald the onset of this disease, followed by septic shock and multisystem organ failure.

**Clinical Features**

Diagnosis of TSS requires the presence of (1) fever of at least 38.9°C; (2) hypotension, with a systolic blood pressure of 90 mm Hg or less; (3) skin rash; and (4) involvement of at least three organ systems. Systemic involvement may include the gastrointestinal (GI) tract, muscular system, or central nervous system (CNS) and laboratory evidence of renal, hepatic, or hematologic dysfunction. Headache, myalgias, arthralgia, alteration of consciousness, nausea, vomiting, and diarrhea may be present.

The rash is typically a diffuse, blanching, macular erythoderma. Accompanying nonexudative mucous membrane inflammation is common. Pharyngitis, sometimes accompanied by a “strawberry tongue,” conjunctivitis, or vaginitis may be seen. As a rule, the rash fades within 3 days of its appearance. This is followed by a full-thickness desquamation, most commonly involving the hands and feet.

**Management**

Initial treatment of TSS consists of IV fluid replacement, ventilatory support, pressor agents, penicillinase-resistant antibiotics, and drainage of infected sites.

**Urticaria**

**Principles of Disease**

Urticaria may occur in isolation or as part of a systemic anaphylactic reaction. The following discussion pertains to urticaria occurring in the absence of systemic symptoms. Anaphylactic reactions are discussed in Chapter 117. Approximately 15 to 20% of the population experience urticaria during their lifetime. Acute urticaria is seen in both sexes and is more likely to have an allergic cause. Chronic urticaria is more common in women in their 40s and 50s. Half of all patients with chronic urticaria have the disease for 5 years and one fourth for 20 years.

Various mediators, including histamine, bradykinin, kallikrein, and acetylcholine, are thought to play a role in urticaria production. Urticaria may be initiated by immunologic or nonimmunologic mechanisms. Hives found in anaphylaxis and serum sickness represent an immunologic reaction. Nonimmunologic urticaria may be produced by degranulation of mast cells, which may be caused by a number of foods and drugs, including aspirin and narcotics.

Substances that can cause urticaria by contact with the skin include foods, textiles, animal dander and saliva, plants, topical medications, chemicals, and cosmetics. The role of drugs in the production of urticaria is discussed in the section on drug eruption. Almost any drug may produce urticaria, although penicillin and aspirin are the most common. Traces of penicillin may be present in dairy products as well as in medications.

The mechanism of production of urticaria by aspirin is unknown but is probably nonimmunologic, and the effects of aspirin may persist for a number of weeks after ingestion.

A variety of food allergies, such as fish, eggs, or nuts, may result in urticaria. In addition, foods such as lobster and strawberries can release histamine through a nonimmunologic mechanism. Hereditary forms of urticaria include familial cold urticaria and hereditary angioneurotic edema.

Infections are an uncommon cause of urticaria, except in children in whom viral infections often cause hives. Occult infections with *Candida*, the dermatophytes, bacteria, viruses, and parasites may trigger hives. Viral infections that produce urticaria include hepatitis, mononucleosis, and coxsackievirus infections.

The inhalation of pollens, mold, animal dander, dust, plant products, and aerosols may produce urticaria. Respiratory symptoms may accompany the dermatosis, and a seasonal pattern of occurrence may be present. Stings and bites of insects, arthropods, and various marine animals may also produce an urticarial eruption.
Occasionally, patients with systemic lupus erythematosus, lymphoma, carcinoma, hyperthyroidism, rheumatic fever, and juvenile rheumatoid arthritis develop an urticarial eruption. The association is uncommon enough that it is not necessary for a urticaria workup to include a search for malignancy in most cases.

A number of physical agents produce urticaria. Dermatographism is present when firm stroking of the skin produces an urticarial wheal within 30 minutes (Fig. 118-9) and is the most common form of physical urticaria. Pressure urticaria is distinct from dermatographism in that the onset of urticaria is delayed by 4 to 8 hours after the application of physical pressure. There is no other particular significance to this form of urticaria.

Cold urticaria may be either familial or, more commonly, acquired. Cold urticaria may also be associated with underlying illness, such as cryoglobulinemia, cryofibrinogenemia, syphilis, and connective tissue disease. Antihistamines, 2 to 4 mg two or three times a day, is useful in the suppression of primary cold urticaria. Side effects of this drug include drowsiness and an increased appetite. Antihistamines taken 30 to 60 minutes before cold exposure may be helpful. Doxepin is also useful; begin at 10 mg at bedtime and gradually increase to 10 to 25 mg three times a day.

Cholinergic urticaria is induced by exercise, heat, or emotional stress. It may be associated with pruritus, nausea, abdominal pain, and headache. The lesions of cholinergic urticaria are wheals 1 to 3 mm in diameter surrounded by extensive erythematous flares and, occasionally, satellite wheals. Cholinergic urticaria responds better to hydroxyzine than do other physical urticarias.

Heat is a rare cause of hives. Solar urticaria, also uncommon, is confined to sun-exposed areas of skin and clears rapidly when the light stimulus is removed. Extensive sun exposure may cause wheezing, dizziness, and syncope in a susceptible individual. Sunscreens have not been proven to be effective for the prevention of solar urticaria.

The cause of chronic urticaria in adults is often not determined, although the etiologic factors responsible for urticaria in children are more readily identifiable.

Clinical Features

Urticaria appears as edematous plaques with pale centers and red borders and is easily recognizable (see Fig. 118-5). Individual hives are transient, lasting less than 24 hours, although new hives may continuously develop, which represent localized dermal edema produced by transvascular fluid extravasation.

Differential Considerations

The differential diagnosis of urticaria includes erythema multiforme, erythema marginatum, and juvenile rheumatoid arthritis.

Management

Treatment of urticaria involves the removal of the inciting factor, when applicable, and the administration of antihistamines or other antipruritics. Hydroxyzine (Atarax and Vistaril) in a dose of 10 to 25 mg (2 mg/kg/24 hr in children) is usually effective in providing symptomatic relief. Alternatives are non-sedating antihistamines, such as terfenadine 60 mg twice a day, astemizole 10 mg daily, or fexofenadine 60 mg twice a day. Prednisone is also effective, but the urticaria can rebound, making cessation of prednisone sometimes difficult. For chronic urticaria, long-term therapy with antihistamines may be needed.

Serum Sickness

Serum sickness is a clinical syndrome most commonly caused by drugs and characterized by fever, lymphadenopathy, arthralgias, cutaneous eruptions, gastrointestinal disturbances, and malaise. It is often associated with proteinuria, without evidence of glomerulonephritis. A widespread morbilliform or urticarial rash or erythema multiforme–like eruption develops, sometimes involving the palms and soles. The most common cause of serum sickness and serum sickness–like reactions is a hypersensitivity reaction to drugs. Cefaclor is a common culprit in causing serum sickness–like reactions.

Serum sickness usually begins 1 to 3 weeks after the start of administration of the medication, although it can occur within 12 to 36 hours in individuals who have been sensitized during a previous exposure. Serum sickness is mediated by the tissue deposition of circulating immune complexes, the activation of complement, and the ensuing inflammatory response. This is a type III (immune complex) reaction, or Arthus reaction.

Management

Discontinuation of the culprit drug and symptomatic treatment with antihistamines and topical corticosteroids are recommended. A short course of oral corticosteroids may be required in patients with more severe symptoms. The drug causing the reaction should be avoided in the future. For cefaclor and cefprozil, the risk of cross-reaction with other ß-lactam antibiotics is small, and the further administration of another cephalosporin is usually well tolerated. However, some clinicians recommend that patients who experience serum sickness–like reactions from cefaclor avoid all ß-lactam drugs.

EXANTHEMS

Principles of Disease

An exanthem is defined as a skin eruption that occurs as a symptom of a general disease. Approximately 30 enteroviruses, predominantly the coxsackievirus and echovirus groups, and four types of adenoviruses are known to produce exanthems. Other viruses may do so as well. The exanthems of the coxsackievirus and echovirus are most thoroughly documented. Most viral exanthems are maculopapular, although scarlatiniform, erythematous, vesicular, and petechial rashes
Measles

Clinical Features

Measles is a highly contagious viral illness spread by contact with infectious droplets, with an incubation period of 10 to 14 days. Patients are contagious from 1 or 2 days before onset of symptoms up to 4 days after the appearance of the rash. Symptoms begin with fever and malaise. The fever usually increases daily in a stepwise manner until it reaches approximately 40.5°C on the fifth day of the illness. Cough, coryza, and conjunctivitis begin within 24 hours of the onset of symptoms.

On the second day of the illness, Koplik’s spots, which are pathognomonic of the disease, appear on the buccal mucosa as small, irregular, bright red spots with bluish-white centers. Beginning opposite the molars, Koplik’s spots spread to involve a variable extent of the oropharynx.

The cutaneous eruption of measles begins on the third to fifth day of the illness. Maculopapular erythematous lesions involve the forehead and upper neck and spread to involve the face, trunk, arms, and finally the legs and feet. Koplik’s spots begin to disappear coincident with the appearance of the rash. By the third day of its presence, the rash begins to fade, doing so in the order of its appearance, and the fever subsides.

Complications include otitis media, encephalitis, and pneumonia. Otitis media is the most common complication. Encephalitis occurs in approximately 1 in 1000 cases of measles and carries a 15% mortality. Measles pneumonia may also be life threatening.

Management

If bacterial invasion occurs with otitis or pneumonia, the use of antibiotics is indicated. Otherwise, treatment is supportive. Isolation of infected children is of limited value because exposure usually occurs before the appearance of the rash and the presence of Koplik’s spots renders the disease diagnosable. Measles is not contagious after the fifth day of the presence of the rash. Infection confers lifelong immunity.

The illness can be modified or prevented by the administration of human immune serum globulin (ISG) in a susceptible person within 6 days of exposure. The recommended dose of ISG is 0.25 mL/kg IM in children. Live measles virus vaccine given within 72 hours of exposure may be effective in preventing measles. Some authors suggest vitamin A soon after exposure. The incidence of measles has decreased since the resurgence seen in 1989 to 1991. The patterns observed during outbreaks include a shift from preschool-aged children to older adults and among groups who do not routinely obtain vaccination, such as immigrants.

Rocky Mountain Spotted Fever

Principles of Disease

Rocky Mountain spotted fever is caused by Rickettsia rickettsii, an organism harbored by a variety of ticks. The organism is transmitted to humans through tick saliva at the time of a tick bite or when the tick is crushed while in contact with the host. Although originally described in the Rocky Mountain region, this disease occurs in other areas of North, South, and Central America. Most reported cases are from the southeastern United States.

Clinical Features

The onset of the illness is usually abrupt, with headache, nausea and vomiting, myalgias, chills, and a fever spiking to 40°C. Occasionally, the onset is more gradual, with progressive anorexia, malaise, and fever. The disease may last 3 weeks and may be severe with prominent CNS, cardiac, pulmonary, GI, renal, and other organ involvement; disseminated intravascular coagulation; or shock.

The rash develops on the second to fourth day or, occasionally, as late as the sixth day of the illness. It begins with erythematous macules that blanch on pressure, appearing first on the wrists and ankles. These macules spread up the extremities and to the trunk and face in a matter of hours. They may become petechial or hemorrhagic. Lesions on the palms and soles are particularly characteristic. Increased capillary fragility and splenomegaly may be present.

Diagnostic Strategies

The Weil-Felix reaction is the best known serologic diagnostic test, but the development of Weil-Felix agglutinins in cases of Rocky Mountain spotted fever is not constant, and more specific immunofluorescent procedures have been developed. Treatment should not await the result of such tests, however, but should begin as soon as the disease is suspected on clinical grounds.

Management

Tetracycline (25–30 mg/kg/day in divided doses) is the antibiotic of choice. If the patient is unable to take oral medications, tetracycline may be administered IV, with a 15 mg/kg loading dose followed by a maintenance dosage of 15 mg/kg/day. Doxycycline may be used as well in a dosage of 4.4 mg/kg/day divided every 6 hours followed by 1.1 mg/kg twice a day, up to 30 mg/day. Chloramphenicol may be used for patients allergic to tetracycline and in children younger than 9 years. A usual course is 6 to 10 days and should continue for 72 hours after defervescence. Sulfa drugs should be avoided because they can exacerbate the illness. Rickettsiae are routinely resistant to penicillins, cephalosporins, aminoglycosides, and erythromycin.
Roseola Infantum

Roseola infantum, otherwise known as exanthem subitum or sixth disease, is a benign illness caused by human herpesvirus 6 and characterized by fever and a skin eruption. A roseola-like illness has occasionally been associated with other illnesses. Ninety-five percent of cases are seen in children 6 months to 3 years of age, and most of these are in infants younger than 2 years. A febrile seizure may occur. The fever typically has a 2 years. A febrile seizure may occur. The fever typically has

3 years of age, and most of these are in infants younger than 2 years. A febrile seizure may occur. The fever typically has

an abrupt onset, rising rapidly to 39°C to 41°C, and is present consistently or intermittently for 3 or 4 days, at which time the temperature drops precipitously to normal.

The rash appears with defervescence. The lesions are discrete pink or rose-colored macules or maculopapules 2 or 3 mm in diameter, which blanch on pressure and rarely coalesce. The trunk is involved initially, with the eruption typically spreading to the neck and extremities. Occasionally, the eruptions are limited to the trunk. The rash clears over 1 or 2 days without desquamation.

Despite the presence of a high fever, the infant usually appears well. Encephalitis is a very rare complication. The prognosis is excellent, and no treatment is necessary.

Rubella

Rubella, or German measles, is a viral illness characterized by fever, skin eruption, and generalized lymphadenopathy. It is spread by droplet contact, and peak incidence is in the winter and early spring. The incubation period is typically 14 to 21 days, and the rash heralds the onset of the illness in children. The maximum time of communicability is in the few days before and 5 to 7 days after the onset of the rash. Infants with congenital rubella can shed virus for more than 1 year. In adults, a 1- to 6-day prodrome of headache, malaise, sore throat, coryza, and low-grade fever precedes the rash. These symptoms generally disappear within 24 hours after the appearance of the skin eruption.

The rash of pink to red maculopapules appears first on the face and spreads rapidly to the neck, trunk, and extremities. Those on the trunk may coalesce, but lesions on the extremities do not. The rash remains for 1 to 5 days, classically disappearing at the end of 3 days. Although clearing may be accompanied by fine desquamation, this sign is usually absent.

Lymphadenopathy may begin as early as 1 week before the rash. Although this is generalized, the nodes most apparent are the suboccipital, postauricular, and posterior cervical groups. Palpable adenopathy may be apparent several weeks after other signs and symptoms have subsided.

The major complications of rubella include encephalitis, arthritis, and thrombocytopenia. The most severe complication is fetal damage. A total of 24% of infected fetuses have a congenital defect. A maternal infection may be determined by obtaining serum for hemagglutination inhibition antibody determinations, acutely and in 2 weeks. A fourfold rise in the titer is diagnostic of rubella infection. The routine use of post-exposure prophylaxis of rubella in an unvaccinated woman in early pregnancy is not recommended.

No treatment is required in many cases of rubella. Antipyretics are usually adequate for the treatment of headache, arthralgias, and painful lymphadenopathy.

Erythema Infectiosum

Erythema infectiosum, or fifth disease, is caused by parvovirus B19 infection. It is characterized by mild systemic symptoms, fever in 10 to 15% of patients, and a characteristic rash. Arthralgia and arthritis occur commonly in adults but rarely in children. The rash is intensely red on the face and gives a “slapped-cheek” appearance with circumoral pallor. A maculopapular lace-like rash, which may be noted on the arms, moves caudally to the trunk, buttocks, and thighs. The rash may recur with changes in temperature and exposure to sunlight. The incubation period is usually between 4 and 14 days.

Parvovirus B19 infection may also result in asymptomatic infection, upper respiratory infection, atypical rash, and arthritis without rash.

Rarely, it has been reported to cause hepatitis. Infected immunodeficient patients may experience chronic anemia as a result of this disease. Patients with sickle cell disease or other hemolytic anemias may develop an aplastic crisis lasting 7 to 10 days. Parvovirus B19 infection during pregnancy can cause fetal hydrops and death. No congenital anomalies have been reported. No treatment is required.

Scarlet Fever

Clinical Features

The incidence of scarlet fever has declined in recent years. The illness has an abrupt onset with fever, chills, malaise, and sore throat followed within 12 to 48 hours by a distinctive rash that begins on the chest and spreads rapidly, usually within 24 hours. Circumoral pallor may be noted. The skin has a rough sandpaper-like texture because of the multitude of pinhead-sized lesions. The pharynx is injected, and there may be erythematous lesions or petechiae on the palate. After the resolution of symptoms, desquamation of the involved areas occurs and is characteristic of the disease.

Complications include the development of a streptococcal infection of lymph nodes, tonsils, the middle ear, and the respiratory tract. Late complications include rheumatic fever and acute glomerulonephritis (Fig. 118-10).

Management

Treatment is aimed at providing adequate antistreptococcal blood antibiotic levels for at least 10 days. Oral penicillin VK 50 mg/kg/day (40,000–80,000 units) in four divided doses in children or 250 mg four times a day in adults is administered. Benzathine penicillin (given as Bicillin CR) is administered IM. In patients weighing less than 30 pounds, 300,000 units of benzathine penicillin is used; in patients weighing 31 to 60 pounds, 600,000 units is used. In patients weighing 61 to 100 pounds, 1.2 million units is used. Figure 118-10. Erythema marginatum associated with rheumatic fever. (Courtesy of David Effron, MD.)
pounds, 600,000 units of benzathine is used; in patients weighing 61 to 90 pounds, 900,000 units of benzathine is used; and in those weighing more than 90 pounds, 1.2 million units of benzathine is used. In patients allergic to penicillin, 250 mg of erythromycin four times a day or 40 mg/kg/day should be given orally for 10 days. Other macrolides and certain other cephalosporins may also be used.

PAPULAR LESIONS

Contact Dermatitis

Principles of Disease

Contact dermatitis is an inflammatory reaction of the skin to a chemical, physical, or biologic agent. The inducing agent acts as an irritant or allergic sensitizer. Allergic contact dermatitis is a form of delayed hypersensitivity mediated by lymphocytes sensitized by the contact of the allergen to the skin. It is less common than irritant contact dermatitis. Caustics, industrial solvents, and detergents are common causes of irritant dermatitis. Dermatitis may result from brief contact with a potent caustic or from repeated or prolonged contact with milder irritants.

Clothing, jewelry, soaps, cosmetics, plants, and medications contain allergens that commonly cause allergic contact dermatitis. The most common allergens include rubber compounds, plants of the Rhus genus (poison ivy, oak, and sumac), nickel (often used in jewelry alloys), paraphenylenediamine (an ingredient in hair dyes and industrial chemicals), and ethylenediamine (a stabilizer in topical medications). Sensitization to poison ivy results in sensitization to other plants in this family, such as cashew, mango, lacquer, and ginkgo trees.

Clinical Features

The primary lesions of contact dermatitis are papules, vesicles, or bullae on an erythematous bed. Of the allergens, Rhus species are the most likely to cause bullous eruptions. Oozing, crusting, scaling, and fissuring may be found, along with lichenification in chronic lesions. The distribution of the eruption depends on the specific contactant and may be localized, asymmetric linear, or unilateral (Figs. 118-11 and 118-12). Mucous membranes are usually spared unless directly exposed to the inciting agent. A history of exposure is the most significant factor favoring the diagnosis. If doubt exists about the diagnosis, the patient should be referred for allergic patch testing.

Management

Treatment of contact dermatitis includes avoidance of the irritant or allergen and treatment of secondary bacterial infection. Oozing or vesiculated lesions should be treated with cool wet compresses of Burow’s solution applied for 15 minutes three or four times a day. Topical baths, available over the counter, may also be comforting. A course of systemic corticosteroids is often necessary. Prednisone in a dosage of 30 to 80 mg/day (depending on the severity of involvement) should be prescribed initially. This should be tapered over at least 10 to 14 days, and 21 days for poison ivy. The long, slow taper is needed to prevent rebound of the disease. The treatment may be discontinued when a daily dose of 10 mg is reached. Systemic antihistamines, such as hydroxyzine or diphenhydramine, may help control pruritus.

The patient should also be counseled to wash all clothes that might have contacted the plant because the irritant plant oil can persist. Once the offending agent is reliably removed from the skin and clothes, ongoing outbreak is attributable to the initial contact, not spread from the serous fluid from the bullae. The patient is not contagious to others unless there is direct contact with the plant oil in people who are sensitized.

Erythema Multiforme

Principles of Disease

The most common precipitating factors in erythema multiforme are exposure to drugs and HSV infection. Other causes include other viral infections, especially hepatitis and influenza A. Less common causes include fungal diseases, such as dermatophytosis, histoplasmosis, and coccidioidomycosis, and bacterial infections, especially streptococcal infections and tuberculosis. Various collagen vascular disorders have been known to precipitate erythema multiforme, particularly rheumatoid arthritis, systemic lupus erythematosus, dermatomyositis, and periarteritis nodosa. Pregnancy and various malignancies have also been associated with erythema multiforme. No provocative factor can be identified in approximately half of all cases. Differential diagnosis includes urticaria, scalded skin syndrome, pemphigus, and pemphigoid and viral exanthems.

Clinical Features

Erythema multiforme is an acute, usually self-limited disease precipitated by a variety of factors. It is characterized by the
sudden appearance of skin lesions that are erythematous or violaceous macules, papules, vesicles, or bullae. Their distribution is often symmetrical, most commonly involving the soles and palms, the backs of the hands or feet, and the extensor surfaces of the extremities. The presence of lesions of the palms and soles is particularly characteristic.\(^{31}\)

The target lesion with three zones of color is the hallmark of erythema multiforme. It is a central, dark papule or vesicle that is surrounded by a pale zone, a halo of erythema (Fig. 118-13), and is commonly found on the hands or wrist.

Stevens-Johnson syndrome, a severe form of erythema multiforme, is occasionally fatal. It is characterized by bullae, mucous membrane lesions, and multisystem involvement (Fig. 118-14). The patient may be toxic; complaining of chills, headache, and malaise; and displaying fever, tachycardia, and tachypnea. Systemic involvement may occur, with renal, GI, or respiratory tract lesions, resulting in hematuria, diarrhea, bronchitis, or pneumonia. Purulent conjunctivitis may be severe enough to cause the eyes to swell shut. Death results from infection and dehydration.

**Management**

Treatment should begin with a search for the underlying cause. Mild forms resolve spontaneously in 2 or 3 weeks. Severe cases may last up to 6 weeks and may require hospital admission for IV hydration, local skin care, systemic analgesia, and systemic corticosteroid therapy, which should consist of 80 to 120 mg of prednisone daily in divided doses. Bullous lesions should be treated with the application of wet compresses soaked in a 1:16,000 solution of potassium permanganate or a 0.05% silver nitrate solution several times a day. The major complications of Stevens-Johnson syndrome are infection and fluid loss. Renal involvement and pneumonia are rare. Severe conjunctivitis may result in corneal scarring and blindness. Reported mortality rates for Stevens-Johnson syndrome range from 0 to 15%.\(^{3,15}\)

**Pediculosis**

**Clinical Features**

The diagnosis is made by identification of nits or adult lice on microscopic examination of plucked hairs from the symptomatic area. Nits are relatively more common than the adult louse form. Nits attach to the bases of hair shafts and appear as white dots (Fig. 118-15). Adult forms look like blue or black grains. The patient complains of intense itching and scratching. A secondary infection may result from the latter.

The organisms causing pediculosis corporis reside in the seams of clothing and bedding materials while they feed on the human host. Except for heavily infested individuals, the parasites are absent from the body. Erythematous macules or wheals may be present, along with intense pruritus. The treatment consists of laundering or boiling clothing and bed linen. If nits are found in the body hair, a treatment with lindane lotion may be instituted, but this is not necessary in most cases (Figs. 118-16 and 118-17).

Pediculosis capitis is seen more commonly in small children than in adults. Pruritus is the major symptom and may be confined to the occipital or postauricular scalp. Excoriations commonly result in secondary bacterial infections and regional lymphadenopathy.

**Diagnostic Strategies**

The diagnosis is made by the identification of nits cemented to hairs at the hair-scalp junction (see Fig. 118-15).

**Management**

Lindane (Kwell) lotion or cream is no longer the preferred prescription topical treatment.\(^{77}\) Permethrin (Nix) is the recommended treatment. It remains active for 2 weeks. Creme rinses and conditioning shampoos should not be used during this period because they coat the hairs and protect the lice from the insecticide. Permethrin is applied to the scalp after...
household members need not undergo a course of therapy. Underclothing, pajamas, and sheets and pillowcases should be machine washed (hot water) and dried, laundered and ironed, or boiled. Pruritus that persists after the course of therapy may result from an irritation of the skin by the pediculicide, sensitization, or patient anxiety.

Permethrin is used to treat pediculosis capitis. A single dose of oral ivermectin, 200 µg/kg repeated in 10 days, has been shown to eradicate head lice.77 Lindane should be reserved for treatment failures. Household contacts should be examined for involvement, but uninfected persons need not be treated.

Scabies

Clinical Features

Scabies is a mite infestation characterized by severe itching, which usually worsens at night. The areas of the body most commonly involved are the interdigital web spaces, flexion areas of the wrists, axillae, buttocks, lower back, penis, scrotum, and breasts (Fig. 118-18). The infestation tends to be more generalized in infants and children than in adults. The typical lesions are reddish papules or vesicles surrounded by an erythematous border and scratch marks. Scabies in infants and young children often have generalized skin involvement, including the face, scalp, palms, and soles. In infants, the most common presenting lesions are papules and vesiculopustules.78

Nodular scabies is a clinical variant in which extremely pruritic nodules are present on the male genitalia, buttocks, groin, and axillary regions. The nodules are reddish to brown, do not contain mites, and are thought to represent hypersensitivity reactions. They can persist for weeks despite adequate scabicidal treatment.

Immunosuppressed patients may develop Norwegian scabies, which is manifested by extensive hyperkeratosis and crusting of the hands, feet, and scalp. It is highly contagious because of excessive mite proliferation.79,80 Secondary infections of these lesions are common.

Close personal contact is involved in transmission of scabies. Multiple family members are likely to become infested. The infestation is also transmitted with sexual contact.

Management

Treatment options include crotamiton (Eurax) lotion and cream or permethrin 5% cream (Elimite) and ivermectin. Lindane is no longer the preferred treatment. Patients in
whom the former treatment fails may respond to the latter. Permethrin 5% cream (Elimite) applied overnight once weekly for 2 weeks over the entire body is the treatment of choice for infants and small children. It is more effective than crotamiton (Eurax) in eliminating the mite, in reducing secondary bacterial infection, and in reducing pruritus. Postscabetic nodules and pruritus may persist for months, even after successful treatment. Treatment of Norwegian scabies may require repeated treatment with scabicides and sometimes sequential use of several agents.

A single dose of oral ivermectin, 200 µg/kg, may also be used. A second dose given 1 week later has been demonstrated to substantially improve the cure rate. Patients with crusted scabies may require repeat doses of ivermectin (200 µg/kg) along with topical scabicides (full-body application, repeated initially every few days) and keratolytics.

The full benefit of ivermectin becomes evident when eradication of scabies in epidemic or endemic situations is needed since ivermectin leads to reliable disease control. The safety of ivermectin has been documented in millions of people with microfilarial diseases. Although ivermectin does not normally penetrate the blood-brain barrier and there should be no risk of seizures, neurotoxicity has been reported in the elderly. Because of limited safety data, ivermectin should not be used in children younger than 5 years or during pregnancy or lactation.

The essential oil of the tea tree (Melaleuca alternifolia) and the essential oil of the Lippia multiflora Moldenke have also been noted to have scabicidal and antibacterial activity, although the dosing schedule of tea tree oil has not been established.

All family members and sexual contacts should also be treated. Intimate articles of clothing and sheets and pillowcases should be washed and dried by machine (hot water), laundered and ironed, or boiled.

It may take several weeks after therapy for the signs and symptoms to abate. A hypersensitivity state or anxiety may prolong symptoms long after the mites have been destroyed.

**Syphilis**

**Clinical Features**

Syphilis is transmitted only by direct contact with an infectious lesion. The causative organism is the spirochete Treponema pallidum. After an incubation period of 10 to 90 days, the primary lesion appears, which lasts from 3 to 12 weeks and heals spontaneously. In 6 weeks to 6 months after exposure, the disease enters the secondary stage, which involves a variety of mucocutaneous lesions. These lesions also heal spontaneously in 2 to 6 weeks as the disease enters the latent phase. Either a prolonged latent phase or tertiary syphilis follows. Of untreated patients, 25% display at least one relapse of mucocutaneous lesions of the oral cavity or anogenital region.

The chancre is the dermatologic manifestation of primary syphilis. Chancres usually appear as single lesions but may be multiple. They appear at the site of spirochete inoculation, usually the mucous membranes of the mouth or genitalia. The chancre begins as a papule and characteristically develops into an ulcer approximately 1 cm in diameter with a clean base and raised borders. The chancre is painless unless secondarily infected, and it may be accompanied by painless lymphadenopathy.

The secondary stage usually follows the primary stage by 6 weeks or more but rarely overlaps primary syphilis. There are a number of cutaneous manifestations of secondary syphilis. Lesions may be erythematous or pink macules or papules, usually with a generalized symmetrical distribution (Fig. 118-19). Pigmented macules and papules classically appear on the palms and soles (Figs. 118-20 and 118-21). The lesions may be scaly but are rarely pruritic.

Papular, annular, and circinate lesions are more common in people of color. Generalized lymphadenopathy and malaise accompany the skin lesions. Irregular, patchy alopecia may be seen. Moist, flat, verrucous condyloma latum may appear in the genital area. These lesions are highly contagious.
Diagnostic Strategies

The diagnosis of primary syphilis is made primarily by the identification of spirochetes with darkfield microscopy. Because a darkfield microscope is often not available to the emergency physician, the diagnosis of primary syphilis must be suspected on clinical grounds and the patient referred to a dermatologist or appropriate public agency for diagnosis and treatment. The Venereal Disease Research Laboratory (VDRL) test, the most commonly used diagnostic serologic test, is positive in approximately three fourths of patients with primary syphilis, but the test tends to be negative early in the course of the disease.33

The VDRL test is invariably positive in cases of secondary syphilis, usually in titers of 1:16 or greater. The darkfield examination of moist lesions may also be positive, but the diagnosis in this stage is based on a positive serologic test. The most specific and sensitive serologic test is the fluorescent treponemal antibody absorption (FTA-ABS) test.33

A biologic false-positive serologic test for syphilis is defined as a positive VDRL test with a negative FTA-ABS test. This situation is seen acutely after vaccination or infections, especially mycoplasmal pneumonia, mononucleosis, hepatitis, measles, varicella, and malaria, and in pregnancy. Chronic biologic false-positive reactions (i.e., those lasting longer than 6 months) may occur with systemic lupus erythematosus, thyroiditis, lymphoma, narcotic addiction, or in elderly patients. Most false-positive reactions are in low titer ranges of 1:1 to 1:4.

Management

Incubating syphilis, the stage before the appearance of primary lesions, may be treated with 4.8 million units of procaine penicillin IM after 1 g of probenecid orally. Primary and secondary syphilis is treated with benzathine penicillin G in a dose of 2.4 million units IM. Patients allergic to penicillin should be treated for 14 days with doxycycline, 100 mg twice a day, tetracycline, 500 mg four times a day, or erythromycin, 500 mg four times a day.32 HIV-infected patients require more intensive therapy.

Treatment may be administered in the ED if the diagnosis can be made on clinical, microscopic, or serologic grounds. If this cannot be done, a serologic sample should be drawn and the patient referred for treatment. The VDRL test may be expected to return to nonreactive 6 to 12 months after the treatment of primary disease or 1 to 11/2 years after the treatment of secondary disease. Patients with tertiary syphilis who are adequately treated may nevertheless retain a positive serologic result. Within 12 hours of receiving therapy, patients may experience a febrile reaction and diffuse rash called the Jarisch-Herxheimer reaction. The reaction resolves spontaneously, usually within 24 hours.

NODULAR LESIONS

Erythema Nodosum

Clinical Features

Erythema nodosum is an inflammatory reaction of the dermis and adipose tissue that is seen with painful red to violet nodules. Nodules are elevated lesions located deep in the skin, and the skin over the nodules can be moved by palpation. These painful nodules occur most commonly over the anterior tibia but may also be seen on the arms or body. Fever and arthralgia of the ankles and knees may precede the rash.33 As the lesions evolve, they may turn yellow-purple and resemble bruises (Fig. 118-22). Women are affected three times more often than men, with the highest incidence in the third to fifth decades of life.68

A number of underlying conditions produce erythema nodosum: tuberculosis, sarcoidosis, coccidioidomycosis, histoplasmosis, ulcerative colitis, regional enteritis, pregnancy, infections with streptococci, Yersinia enterocolitica, and Chlamydia. As with erythema multiforme, many cases of erythema nodosum are idiopathic. The relationship of drugs to erythema nodosum was noted in the section on drug eruption. Oral contraceptive agents are a leading cause of drug-induced cases. The differential diagnosis includes traumatic bruises and subcutaneous fat necrosis.

Management

When an underlying condition can be determined, this should be treated as indicated. Chest radiograph may be considered to rule out sarcoidosis, tuberculosis, or deep fungal infection. Bed rest, elevating the legs, and wearing elastic stockings reduce pain and edema. Aspirin in a dosage of 600 mg every 4 hours or nonsteroidal anti-inflammatory agents may also afford some relief.33 Erythema nodosum is a self-limited process that usually resolves in 3 to 8 weeks.7 Patients with severe pain may be treated with 360 to 900 mg of potassium iodide daily for 3 or 4 weeks. Stopping therapy before this time may result in a relapse. Potassium iodide may act through an immunosuppressive mechanism mediated via heparin release from mast cells.33

VESICULAR LESIONS

Perspective

Vesicles are elevated lesions that contain clear fluid. Vesicles greater than 1 cm are known as bullae. Vesicles may sometimes be associated with red papular lesions, as in contact dermatitis or erythema multiforme.

Pemphigus Vulgaris

Clinical Features

Pemphigus vulgaris is an uncommon, but important, dermatologic disorder. The mortality rate before the use of steroids was approximately 95%. The current mortality rate is 10 to
15%, related more to steroid-induced complications than to the disease. Pemphigus is a bullous disease, affecting both sexes equally, and is most common in patients 40 to 60 years old. The disease is mostly prevalent in people of Jewish, Mediterranean, or south Asian descent. The typical skin lesions are small, flaccid bullae that break easily, forming superficial erosions and crusted ulcerations. Any area of the body may be involved. Nikolsky’s sign is present and characteristic of the disease. Blisters may be extended or new bullae may be formed by firm tangential pressure of a finger on the intact epidermis.

Before the appearance of the skin involvement, mucous membrane lesions occur; 50 to 60% of patients have oral lesions. The oral lesions typically antedate the cutaneous lesions by several months. The most common site is in the mouth, especially the gums and vermilion borders of the lips. Oral lesions are bullous but commonly break, leaving painful, denuded areas of superficial ulceration.

The cause of pemphigus is unknown, although studies suggest an autoimmune mechanism. The development of pemphigus has been associated in a few instances with the use of medications, most notably penicillamine and captopril. A positive Tzanck cytologic test suggests the diagnosis (i.e., finding acantholytic cells or degenerated, rounded epithelial cells with amorphous nuclei). Acantholytic cells are not specific for pemphigus, however, and the diagnosis must be confirmed by serum immunofluorescence. The differential diagnosis includes bullous pemphigoid, epidermolysis, dermatitis herpetiformis, toxic epidermal necrolysis, bullous scabies, and bullous systemic lupus erythematosus.

Management

Pain control and local wound care are essential components of therapy. Once the diagnosis is made, treatment with oral glucocorticoids in initial doses of 100 to 300 mg of prednisone, or an equivalent drug, should be instituted in conjunction with a dermatologist. Other immunosuppressant drugs may also be used. Despite the condition’s localization to the skin and mucous membranes, death was the rule before treatment with steroids, and the mortality rate continues to be substantial. Deaths are related to an uncontrolled spread of the disease, secondary infection, dehydration, and thromboembolism. Other medical illnesses, as well as the side effects of high-dosage corticosteroids, also contribute to mortality.

Herpes Simplex

Perspective

Two known variants of HSV cause human infection: HSV-1 and HSV-2. The former primarily affects nongenital sites, whereas lesions caused by the latter are found predominantly in the genital area and are transmitted primarily by venereal contact.

Clinical Features

The hallmark of skin infection with HSV is painful, grouped vesicles on an erythematous base. Those above the waist are usually caused by HSV-1, whereas those below the waist generally result from HSV-2. The lesions are usually localized in a nondermatomal distribution. The skin distribution may become more generalized in patients with atopic eczema and other dermatoses. Adults with HSV infection should avoid contact with children with atopic dermatitis, especially in the first 3 to 5 days of infection.
The mouth is the most common site of HSV-1 infections. Children are affected more commonly than adults. Small clusters of vesicles may be present. The severity of gingivostomatitis varies from the presence of small ulcers to extensive ulceration of the mouth, tongue, and gums accompanied by fever and cervical lymphadenopathy. The infection may be so severe that oral fluid intake is difficult, and dehydration may result. Healing typically occurs in 7 to 14 days, unless a secondary infection with streptococci or staphylococci occurs.

HSV-2 infections in men are seen with either single or multiple vesicles on the shaft or glans penis. Fever, malaise, and regional adenopathy may be present. A prodrome of local pain and hyperesthesia may precede the appearance of the cutaneous lesions. The vesicles erode after several days, become crusted, and heal in 10 to 14 days. Infections in women involve the introitus, cervix, or vagina. Vesicles may be grouped or confluent. Herpetic cervicitis or vaginitis may be the cause of severe pelvic pain, dysuria, or vaginal discharge. Recurrence is common, but recurrent episodes tend to be less severe. A correlation based on serologic and epidemiologic data has been discovered between HSV-2 reproductive tract infections and carcinoma of the cervix.

Management

Recommended treatment for a first clinical episode of genital herpes is with acyclovir (Zovirax), 200 mg orally five times a day for 7 to 10 days, famciclovir, 125 mg twice a day, or valacyclovir, 500 mg three times a day or until clinical resolution occurs. These agents reduce the duration of viral shedding, accelerate healing, and shorten the duration of symptoms, but they have not succeeded in preventing recurrent episodes. Prophylactic administration of acyclovir may be effective in ameliorating the severity of recurrent genital herpes, but the effects of long-term administration are unknown. Although many episodes of recurrent herpes infection do not benefit from acyclovir therapy, 200 mg five times a day may be given orally for recurrences at the beginning of the prodrome. Famciclovir, 125 mg twice a day for 5 days, and valacyclovir, 500 mg three times a day for the same duration, are equally effective.

Severe initial attacks of genital herpes have been successfully treated with the IV infusion of acyclovir. Admission to the hospital is required, however, because such treatment is necessary for several days, especially for the immunocompromised patient. A mucocutaneous herpes infection in such patients is potentially fatal because it has a propensity for generalization and dissemination to the internal organs.

Supportive care is important and pain control is a major concern. Systemic analgesics and topical anesthetic agents may be useful. Patient education regarding the prevention or spread of the disease during sexual contact and the birth process is imperative.

Varicella

Clinical Features

Varicella, or chickenpox, is an infection caused by the varicella-zoster virus. After an incubation period of 14 to 21 days, the illness begins with a low-grade fever, headache, and malaise. The exanthem coincides with these symptoms in children and follows them by 1 or 2 days in adults.

The skin lesions rapidly progress from macules to papules to vesicles to crusting, sometimes within 6 to 8 hours. The vesicle of varicella is 2 or 3 mm in diameter and surrounded by an erythematous border (Fig. 118-26). An unusual form of varicella presents with larger bullae (Fig. 118-27). The drying of the vesicle begins centrally, producing umbilication. The dried scabs fall off in 5 to 20 days.

Lesions appear in crops on the trunk, where they are seen in the highest concentration, and on the scalp, face, and extremities. The hallmark of varicella is the appearance of lesions in all stages of development in one region of the body. Extensive eruptions are often associated with a high and prolonged fever.

Complications of chickenpox include encephalitis or meningitis, pneumonia, staphylococcal or streptococcal cellulitis, thrombocytopenia, arthritis, hepatitis, and glomerulonephritis. Varicella pneumonia occurs more commonly in adults than in children.

Management

The illness is self-limited, and treatment is symptomatic only. Salicylates should be avoided in patients with chickenpox to minimize the risk of subsequent Reye’s syndrome. Oral acyclovir may be effective if it can be started within 24 hours of development of rash for patients with chronic respiratory or skin disease. Some studies report a diminution in duration and magnitude of fever and number and duration of lesions with the early use of acyclovir.

Isolation of infected patients is often futile because the disease may be transmitted before the diagnosis is clinically evident. Because the disease has the potential to be contagious until all vesicles are crusted and dried, infected persons should be kept at home until this stage is reached.
Varicella-zoster and varicella titers should be checked in pregnant women and immunocompromised patients who are exposed to chickenpox, and if negative, varicella-zoster immune globulin should be administered within 96 hours of exposure. Fetal infection after maternal varicella in the first or early second trimester of pregnancy may result in varicella embryopathy, a condition characterized by limb atrophy, scarring on extremities, and CNS and ocular manifestations. Maternal varicella that occurs between 5 days before delivery and 2 days after delivery may result in disseminated herpes in the newborn.

The varicella vaccine is a live attenuated virus; it is highly efficacious and very safe. A single dose is effective in children between the ages of 1 and 13 years. For older children, two doses separated by 4 to 8 weeks is recommended. In addition, the incidence of zoster occurring after vaccination appears to be lower than after naturally acquired disease.

Herpes Zoster

Clinical Features

Herpes zoster, or shingles, is an infection caused by the varicella zoster virus. It occurs exclusively in individuals who have previously had chickenpox. Before the rash appears, the patient typically develops pain in a dermatomal distribution. This pain precedes the eruption by 1 to 10 days; is of variable intensity; and is described as sharp, dull, or burning in quality. The rash consists of grouped vesicles on an erythematous base involving one or several dermatomes. The thorax is involved in most cases, and the trigeminal distribution is the next most commonly involved region.

The vesicles initially appear clear and then become cloudy and progress to scab and crust formation. This process takes 10 to 12 days, and the crusts fall off in 2 or 3 weeks (Figs. 118-28 and 118-29). Herpes zoster has a peak incidence in patients 50 to 70 years old and is unusual in children. Although the association with leukemia, Hodgkin’s lymphoma, and other malignancies is well known, rarely does the appearance antedate the diagnosis of such diseases. Most cases of herpes zoster occur in healthy individuals.

Herpes zoster may be transmitted from patients with chickenpox to susceptible individuals. Chickenpox may also be acquired by contact with shingles, although this is less common. It is generally believed, however, that herpes zoster is caused by a reactivation of latent varicella-zoster virus present since the initial infection with chickenpox. During the latent period between the two illnesses, the virus is thought to reside in dorsal root ganglion cells.

Herpes zoster has a very low mortality rate and is rarely life threatening, even when dissemination to the visceral organs occurs. Complications include CNS involvement, ocular infection, and neuralgia. Meningoencephalitis, myelitis, and peripheral neuropathy have been reported.

Ocular complications occur in 20 to 70% of cases involving the ophthalmic division of the trigeminal nerve. The severity varies from mild conjunctivitis to panophthalmitis, which threatens the eye. Eye involvement produces anterior uveitis, secondary glaucoma, and corneal scarring. There is a close correlation between eye involvement and vesicles located at the tip of the nose.

Postherpetic neuralgia, pain that persists after the lesions have healed, occurs more commonly in elderly and immunosuppressed patients. It may last a number of months and is often resistant to treatment with standard analgesic medications.

Herpes zoster generally tends to be more severe in immunosuppressed patients, especially those with AIDS, Hodgkin’s disease, or other lymphomas. Cutaneous dissemination occurs more commonly in these patients than in the general population. Visceral and CNS dissemination is also more likely to occur in these patients; therefore, they should be considered for hospitalization.

Management

Treatment other than analgesia is rarely necessary. Burow’s solution compresses diluted 1:20 to 1:40 in water may be applied to hasten drying. Early systemic corticosteroid therapy may shorten the duration of postherpetic neuralgia but does not lessen the severity of pain or the rate of the healing of the lesions. Antiviral chemotherapy, with acyclovir, famciclovir, vidarabine, foscarnet, valacyclovir, and interferon-α, has been shown to be effective for immunocompromised patients.

Postherpetic neuralgia is a complicated problem with few satisfactory solutions. Some success has been achieved using capsaicin cream, but this cannot be applied to inflamed or eroded skin.

Intravenous acyclovir may be of some benefit in the treatment of severe ocular herpes zoster. Treatment includes mydriasis and the application of topical corticosteroids. Unlike the situation with herpes simplex conjunctivitis, eye involvement caused by herpes zoster does not appear to be exacerbated by corticosteroids.

Smallpox

The last naturally occurring case of smallpox was in Somalia in 1977. Subsequently, the routine vaccination of the general public was stopped. Except for laboratory stockpiles, the variola virus had been eliminated. Due to recent concerns regarding biological agents as weapons, it is important that smallpox be differentiated from chickenpox (Table 118-3; Fig. 118-30).91

Cutaneous Anthrax

Cutaneous anthrax begins as a pruritic pustule or vesicle that enlarges and erodes over 1 or 2 days. Subsequently, a necrotic ulcer with central black eschar is formed. The lesion may be painless and may be surrounded by significant edema (Fig. 118-31).

■ SKIN LESIONS ASSOCIATED WITH SYSTEMIC DISEASE

Numerous systemic illnesses have cutaneous manifestations (Table 118-4; Figs. 118-32 to 118-39). Some of the most common illnesses include AIDS, diabetes mellitus, connective tissue diseases, and endocrine disorders.

■ CLINICAL FEATURES OF LESIONS ASSOCIATED WITH INTERNAL MALIGNANCY

Cutaneous lesions most directly indicative of an internal malignancy arise from the extension of the tumor to the skin or by hematogenous or lymphatic metastasis. The neoplasms that most commonly produce such a cutaneous extension are lymphomas, leukemias, and carcinomas of the breast, GI tract, lung, ovary, prostate, uterus, and bladder. Skin metastases generally signify a poor prognosis.93

Acanthosis Nigricans

Acanthosis nigricans is associated with internal malignancy, despite the fact that most patients do not have tumors. Benign cases may be familial or related to endocrine disease or obesity. The term malignant acanthosis nigricans is used to designate the form associated with neoplastic disease. This phrasing is misleading because acanthosis nigricans is only a marker of the underlying disease and is never infiltrated with malignant cells.

The lesion appears as a hyperpigmented verrucous, velvety-like hyperplasia and hypertrophy of the skin accompanied with accentuation of the skin markings. The chief sites of involvement are the body folds, especially the axillae, antecubital fossae, neck, and groin.

More than 90% of cases of “malignant” acanthosis nigricans are associated with intra-abdominal malignancies, of which two thirds are adenocarcinomas of the stomach. Carcinomas of the colon, ovary, pancreas, rectum, and uterus make up the majority of the rest. Regardless of the tumor type, acanthosis
nigricans is associated with tumors that are usually highly malignant and metastasize early.\textsuperscript{93} The mechanism of this dermatosis in cases of internal malignant disease is postulated to be a result of tumor products that bind to and stimulate insulin-like growth factors in the skin.\textsuperscript{77}

**Dermatomyositis**

The incidence of dermatomyositis with malignant disease ranges from 6 to 55\% and is generally higher in older patients. In younger individuals, the appearance of dermatomyositis does not necessarily call for a tumor workup. Tumors commonly associated with dermatomyositis are carcinomas of the breast, ovary, and GI and female genital tracts. Polymyositis occurring alone without the accompanying skin findings is rarely associated with malignancies.\textsuperscript{94}

**Erythema Multiforme**

Erythema multiforme may be associated with acute forms of leukemia. It is seen with acute monocytic, lymphocytic, and granulocytic forms and is also found in chronic leukemias and Hodgkin’s disease.\textsuperscript{9,94}

**Erythema Nodosum**

Erythema nodosum is another reaction found in association with leukemia and Hodgkin’s lymphoma, as well as with metastatic carcinoma and inflammatory bowel disease.\textsuperscript{94}

**Erythroderma**

Generalized erythroderma is almost pathognomonic for Hodgkin’s disease; however, it is also a common skin manifestation of lymphocytic leukemia. Although less common, it is also seen with other forms of leukemia, carcinoma, and mycosis fungoides. The appearance of erythroderma may precede the diagnosis of internal malignant disease by many years. The skin eruption is invariably accompanied by intractable pruritus.\textsuperscript{94}

**Acquired Ichthyosis**

Acquired ichthyosis is a skin condition manifested as generalized dryness of the skin, scaling, and superficial cracking or as hyperkeratosis of the palms and soles. Hodgkin’s disease is the most common malignant disease associated with the nonfamilial form of ichthyosis. Non-Hodgkin’s lymphoma and carcinomas of the breast, lung, colon, and cervix have also been associated with acquired ichthyosis.\textsuperscript{85}

**Pruritus**

Itching may be an important indicator of Hodgkin’s disease, leukemia, adenocarcinoma or squamous cell carcinoma of various organs, carcinoid syndrome, multiple myeloma, and polycythemia vera. It may appear years before the underlying malignancy is identified.\textsuperscript{85} In cases of Hodgkin’s disease, the itching is usually continuous and may be accompanied by a severe burning sensation. Although usually generalized, pruritus commonly begins in the feet and may be limited to the lower extremities. It may be intractable and associated with urticaria, erythroderma, excoriation, or lichenification.

The pruritus of leukemia and systemic carcinoma is generally less severe than that found with Hodgkin’s disease. Nevertheless, itching associated with internal malignant disease may be difficult to control. Conventional anti-H\textsubscript{1} antihistamines, cimetidine, cholestyramine, and cyproheptadine have each been used with variable results.\textsuperscript{94} Occasionally, only the suppression of the tumor is beneficial.

**Purpura**

Purpura is the most common manifestation of acute granulocytic and monocytic leukemia. It may also be associated with myeloma, lymphoma, and polycythemia vera. Although the most common cause of purpura in these conditions is thrombocytopenia secondary to bone marrow infiltration, in some instances the platelet count is normal and the causative mechanism obscure.\textsuperscript{9} Purpura is caused by vascular abnormalities, thrombocytopenia, or other coagulation defects. A variety of diseases and conditions may be the underlying cause, and the treatment should be directed toward this cause whenever possible (Boxes 118-1 and 118-2).\textsuperscript{94,95} Thrombocytopenic and non-thrombocytopenic forms are differentiated by the results of the patient’s platelet count. Serious bleeding seldom occurs if the platelet count is greater than 50,000/mm\textsuperscript{3}. If the platelet count is less than 10,000/mm\textsuperscript{3} or serious bleeding is encountered, platelet transfusion should be initiated. Because of the short circulating half-life of infused platelets, transfusion should be used as a short-term measure only.

Urticaria

Urticaria is occasionally found in Hodgkin’s disease and more rarely in leukemia and internal carcinoma. Cold urticaria may occur with multiple myeloma (Table 118-5).

**CLINICAL FEATURES OF LESIONS ASSOCIATED WITH NARCOTIC ADDICTION**

Individuals who inject opiates and other drugs parenterally develop characteristic skin lesions secondary to such use. Skin lesions have been most extensively described in heroin addicts. Skin tracks, or indurated linear hyperpigmented streaks, are produced by repeated IV injection (Fig. 118-40). They follow the course of the superficial veins used in the injection, most commonly in the antecubital fossae and the dorsa of the hands.

Subcutaneous injection results in round or oval hyperpigmented atrophic depressed scars 1 to 3 cm in diameter (Fig. 118-41). Abscesses, which often require drainage, commonly precede the development of such scars. Hypertrophic scarring

and keloid formation may also occur. Increased pigmentation may occur in sun-exposed areas and at the site of tourniquet applications.

In addition to the characteristic skin lesions associated with drug injection, people who inject intravenous drugs are prone to sharp foreign body retention, pseudoaneurysm, gram-negative local and systemic infections, wound botulism (associated with the use of black tar heroin), and numerous other illnesses.

**Figure 118-41.** Scars from subcutaneous illicit drug injection. (Courtesy of David Effron, MD.)

**KEY CONCEPTS**

- Infection with *C. albicans* can occur normally in infancy, in obese people, during pregnancy, and in old age. In other patients, the following underlying problems should be considered: AIDS and other immunodeficiency states, diabetes and other endocrine imbalances, malignancy, malnutrition, and other debilitating illnesses.
- Rashes that are associated with mucosal lesions, blisters, or desquamating skin are often caused by significant soft tissue infections, drug eruptions, or immune disorders.
- Purpura result from blood leaking from vessels into the skin and do not blanch when pressure is applied. Purpura less than 3 mm in diameter are called petechiae. Nonpalpable purpura are often caused by coagulation defects (usually platelet abnormalities), whereas palpable purpura are usually a sign of vasculitis.
- Diffuse pruritus in the absence of a skin rash may be a sign of underlying malignancy.

ANEMIA

Definition

Anemia is an absolute decrease in the number of circulating red blood cells (RBCs). The diagnosis is made when laboratory measurements fall below accepted normal values (Table 119-1).

In emergency medicine, anemia may be divided into two broad categories: emergent, having immediate life-threatening complications, and nonemergent, with less imminent patient danger. Factors other than the absolute number of circulating RBCs may place the patient in one category or another (e.g., rate of onset and underlying hemodynamic reserve of the patient). Both groups necessitate a sound diagnostic approach, but emergent anemia may require supportive therapy concomitant with or in advance of the definitive diagnosis. Although patients with nonemergent anemia are usually referred to a specialist, they are seen in the hospital often enough to make an understanding of anemia necessary for emergency physicians. The urgency of consultation depends predominantly on the patient’s hemodynamic tolerance of the anemia.

Pathophysiology

The major function of the RBC is oxygen transport from the lung to the tissue and carbon dioxide transport in the reverse direction. Oxygen transport is influenced by the amount of hemoglobin, its oxygen affinity, and blood flow. An alteration in any of the major components usually results in compensatory changes in the other two. For example, a decrease in hemoglobin from anemia is compensated by both inotropic and chronotropic cardiac changes that result in increased blood flow and decreased hemoglobin affinity at the tissue level, thereby allowing more oxygen release. These compensatory responses may collapse because of disease severity or underlying pathologic conditions. The result is tissue hypoxia and eventual cell death.

Anemia often stimulates the compensatory mechanism of erythropoiesis controlled by the hormone erythropoietin. Erythropoietin is a glycoprotein produced in the kidney (90%) and the liver (10%). It regulates the production of RBCs by controlling differentiation of the committed erythroid stem cell. It is stimulated by tissue hypoxia and products of RBC destruction during hemolysis. Erythropoietin levels are elevated in many types of anemia.

Bone marrow contains pluripotent stem cells that can differentiate into erythroid, myeloid, megakaryocytic, and lymphoid progenitors. Erythropoietin enhances the growth and differentiation of erythroid progenitors. When the late normoblast extrudes its nucleus, it still contains a ribosomal network, which identifies the reticulocyte (Fig. 119-1). The reticulocyte retains its ribosomal network for approximately 4 days, of which are spent in bone marrow and 1 in the peripheral circulation. The RBC matures as the reticulocyte loses its ribosomal network and circulates for 110 to 120 days. The erythrocyte is then removed by macrophages that detect senescent signals.

Under steady-state conditions, the rate of RBC production equals the rate of destruction. RBC mass remains constant because an equal number of reticulocytes replace the destroyed, senescent erythrocytes during the same period.

Common sites of blood loss in trauma include the pleural, peritoneal, pelvic, and retroperitoneal spaces. In nontraumatic circumstances, especially in patients on anticoagulants, the gastrointestinal tract, retroperitoneal space, uterus, and adnexa must be considered.

Causes other than blood loss may be responsible for severe anemia of rapid onset. Certain rare hemolytic conditions can cause rapid intravascular destruction of RBCs (Box 119-1). More common are patients with chronic compensated hemolytic anemia (e.g., sickle cell disease), who decompensate with an acute-onset anemia as a result of decreased erythrocyte production triggered by a viral infection.

Beyond red cell destruction, the status of hemoglobin function must be considered. Impaired hemoglobin transport of oxygen is seen in cases of carbon monoxide poisoning. Methemoglobinemia from nitrates, cyanhemoglobin from cyanide, and sulfhemoglobinemia resulting from hydrogen sulfide may severely decrease functional hemoglobin. These patients often have fatigue, altered mental status, shortness of breath, and other manifestations of hypoxia without signs of RBC loss or volume depletion.

Diagnostic Findings in Emergent Anemia

Clinical Features

The most common cause of clinically severe anemia is blood loss. The clinical manifestation of anemia depends on how rapidly the hematocrit falls and also on the patient’s ability to compensate.
Clinical signs and symptoms include tachycardia, decreased blood pressure, postural hypotension, light-headedness, increased heart rate, and increased respiratory rate. Complaints of thirst, altered mental status, and decreased urine output may also be present. The patient’s age, concomitant illness, and underlying hematologic, cerebral, and cardiovascular status tremendously influence the clinical findings. Children and young adults may tolerate significant blood loss with unaltered vital signs until a precipitant hypotensive episode occurs. Pediatric patients may become markedly tachycardic, physiologically attempting to maintain cardiac output, since their ability to increase stroke volume is limited. Elderly patients commonly have underlying disease states that compromise their ability to compensate for blood loss.9

Ancillary Evaluation

Stabilization of emergent anemia commonly runs parallel to assessment. If the signs and symptoms suggest potential life-threatening conditions, intravenous lines are placed and samples for the following initial laboratory tests are drawn:

1. Complete blood count and peripheral smear
2. Blood sample for type and crossmatch
3. Prothrombin time
4. Partial thromboplastin time
5. Electrolyte levels
6. Glucose level (especially if the patient has altered consciousness)
7. Creatinine level
8. Urinalysis for free hemoglobin
9. Clotting and unclotted blood samples for later testing

If possible, a blood sample is obtained for measurement of hematocrit in the emergency department. Although it may take hours before the hematocrit correctly reflects the degree of blood loss, the initial value is useful in determining an initial baseline. Occasionally, this value reveals an underlying anemia with the acute blood loss superimposed. Depending on severity, a blood sample is sent for type and crossmatch. Peripheral smear interpretation is done on pretreatment blood samples. Measurements of coagulation status, electrolytes, glucose, blood urea nitrogen, and creatinine are useful in the diagnosis of underlying disease processes that may relate to the patient's anemia. Values of folate, vitamin B₁₂, iron, total iron-binding capacity, reticulocytes, and direct antiglobulin (Coombs’ test) are altered by transfusion. Therefore, pretreatment samples are best saved.¹¹,¹²

### Diagnostic Findings in Nonemergent Anemia

#### Clinical Features

Nonemergent anemias are usually seen in ambulatory patients complaining of fatigue and feeling “washed out.” Other voiced complaints include irritability, headache, postural dizziness, angina, decreased exercise tolerance, shortness of breath, and decreased libido. When the anemia is of slow onset, the patient may adapt until the hemoglobin is very low. Alternatively, patients with rapid blood loss may experience lightheadedness or syncope even when the measured hemoglobin is not critically low. For patients without evidence of acute bleeding or emergent condition, elements of history and physical examination may help identify the cause (Box 119-3).

Most of these patients do not need immediate stabilization and can be further evaluated as outpatients.

### Ancillary Evaluation

The initial laboratory evaluation includes a complete blood count with leukocyte differential, reticulocyte count, peripheral smear (Fig. 119-2), and RBC indices, including mean corpuscular volume (MCV), mean corpuscular hemoglobin (MCH), and mean corpuscular hemoglobin concentration (MCHC).
RBC indices are useful in classifying anemias caused by a production deficit. Their calculation and normal ranges are provided in Table 119-2. MCV is a measure of RBC size. Decreases and increases reflect microcytosis and macrocytosis, respectively. MCH incorporates both RBC size and hemoglobin concentration. It is influenced by both and is the least helpful of the indices. The MCHC index is a measure of the concentration of hemoglobin. Low values represent hypochromia, whereas high values are noted only in patients with decreased cell membrane relative to cell volume, such as in the case of spherocytosis. An additional index is the RBC distribution width (RDW), which is a measure of the homogeneity of the RBCs measured. RDW is automatically calculated as the standard deviation of MCV divided by MCV multiplied by 100. A normal RDW is 13.5 ± 1.5%. It is useful in differentiating iron deficiency from thalassemia.14

**Microcytic Anemias.** Hypochromic microcytic anemias can be subdivided into deficiencies of the three building blocks of hemoglobin: iron (iron-deficiency anemia [Fig. 119-3]), globin (thalassemia), and porphyrin (sideroblastic anemia and lead poisoning). Anemia of chronic disease, a secondary iron abnormality, rounds out the differential diagnosis. Not all microcytic anemias are the result of iron deficiency, and routine iron therapy for a patient with a low MCV and MCHC is inappropriate.

**Iron-Deficiency Anemia.** Iron deficiency is a frequent cause of chronic anemia seen in the emergency department. It is the most common anemia in women of childbearing age. In older patients, occult blood loss, especially gastrointestinal, may initially appear as iron-deficiency anemia. Because changes in RBC size and hemoglobin content occur only after bone marrow and cytochrome iron stores are depleted, a patient may have early symptoms of iron deficiency (e.g., fatigue) without manifesting changes in RBC structure. Actually, a low MCV is relatively rare in iron-deficiency anemia.

The diagnosis is made by laboratory evaluation of the fasting level of serum iron, serum ferritin, and total iron-binding capacity. The laboratory interpretation and pitfalls are outlined in Table 119-3. A concentrated search for occult blood loss is vital.

Therapy consists of oral iron replacement. A cost-effective form is ferrous sulfate. The dosage is 300 mg for adults (60 mg of elemental iron) or 3 mg/kg/day for children. This medication is generally well tolerated, although it may cause nausea, vomiting, or constipation. Patients should be warned that their stools will be blackened. In rare patients with poor oral tolerance or absorption, parenteral iron therapy may be necessary.

The patient may experience a sense of improvement in as few as 24 hours. Reticulocytosis appears over a 3- or 4-day period in children but may take more than 1 week in adults. The hemoglobin concentration rises on a similar schedule. If such a response does not occur, the patient is noncompliant with the iron supplementation, the blood loss may exceed the replacement, the diagnosis is incorrect, or the diagnosis is partially correct with an additional process complicating the iron deficiency.15,16

Thalassemia. Thalassemia is a genetic autosomal defect reflected by the decreased synthesis of globin chains.17 The globin in hemoglobin is present as two paired chains. Each type of hemoglobin is made up of different globins. For example, normal adult hemoglobin (HbA) is made up of two α chains and two β chains (α2β2). HbA2 is α2δ2, and fetal hemoglobin (HbF) is α2γ2. A separate autosomal gene controls each globin chain. Deletions in this globin gene result in an absence or decreased function of the messenger RNA that codes for the creation of that globin. The various globins (α, β, δ, and γ) may be affected by a number of genetic combinations. The decrease in globin production in thalassemia results in decreased hemoglobin synthesis and ineffective erythropoiesis. The latter is attributable to increased intramarrow hemoysis with destruction of RBCs before they are released. Normal erythropoiesis has a 10 to 20% incidence of ineffective release, with associated intramarrow RBC destruction. This ineffective release of erythropoiesis may double or triple in patients with thalassemia. The cause is believed to be excess chains of the uninhibited globin precipitating in RBCs.17,18

Although many variations in thalassemia are possible, only three are commonly considered. Homozygous β-chain thalassemia (thalassemia major) occurs predominantly in Mediterranean populations. It represents one of the most common single-gene disorders. The disease is characterized by severe anemia, hepatosplenomegaly, jaundice, abnormal development, and premature death. Patients are transfusion dependent and die from iron deposition in tissues, particularly the myocardium, or infection. Treatment is supportive and consists of transfusion and iron-chelating therapy.19,20

Heterozygous β-chain thalassemia (thalassemia minor) is manifested as a mild microcytic hypochromic anemia with target cells seen on the peripheral smear (Fig. 119-4), an MCV commonly more severely lowered than with iron-deficiency anemia, a normal level of serum iron, and an elevated level of HbA2 (α2δ2) on hemoglobin electrophoresis (2–5%). Usually, no treatment is necessary.

α-Thalassemia varies in spectrum from an asymptomatic carrier state to prenatal death. Four gene loci control this range. In the tolerated forms, it is more commonly seen in Asians and African Americans. Microcytosis, hypochromia,
target cells, and basophilic stippling are noted on the peripheral smear. The diagnosis is made with hemoglobin electrophoresis and genetic testing.

Screening for carriers is performed by measurement of RBC indices and estimation of the hemoglobin A₂ concentration. Prenatal diagnosis can be made by analysis of fetal blood and, more recently, by fetal DNA obtained by chorionic villus sampling.

Therapy consists of blood transfusions, which are based on the clinical severity of the anemia. The goals of transfusion therapy include correction of anemia, suppression of erythropoiesis, and inhibition of increased gastrointestinal iron absorption. Iron-chelating therapy, most commonly deferoxamine, is often required to control excess iron stores. Bone marrow transplantation from HLA-identical donors has resulted in disease-free survival in 60 to 90% of recipients, but its role in thalassemia has yet to be determined. Although much interest centers on permanent correction of genetic deficits in thalassemia, gene therapy does not yet exist. 33,21

Sideroblastic Anemia. Sideroblastic anemia involves a defect in porphyrin synthesis. The resultant impaired hemoglobin production causes excess iron to be deposited in the mitochondria of the RBC precursor, but some also circulates. The result is increased serum iron and ferritin levels, with transferrin saturation. The defective heme synthesis results in ineffective erythropoiesis, mild to moderate anemia, and a dimorphic peripheral smear with hypochromic microcytes along with normal and macrocytic cells. 22

Sideroblastic anemia, although found in a rare sex-linked hereditary form, is typically a disease of the elderly. Indeed, the idiopathic form is a common type of refractory anemia in elderly patients. Pallor and splenomegaly may be noted, and iron staining of the peripheral smear may demonstrate iron-containing Pappenheimer inclusion bodies in RBCs. Some of these patients are deficient in pyridoxine (vitamin B₆) and respond to treatment with 100 mg of pyridoxine three times a day. Most remain anemic, but a 1- or 2-month pyridoxine trial is acceptable treatment. These patients may be susceptible to iron overload, particularly if long-term transfusion therapy is necessary, but they may respond to iron chelation therapy. Idiopathic sideroblastic anemia is considered a preleukemic state, and acute myelogenous leukemia develops in approximately 20% of these patients.

Secondary causes of sideroblastic anemia include toxins such as chloramphenicol, isoniazid, and cycloserine, as well as diseases such as hemolytic and megaloblastic anemia, infection, carcinoma, leukemia, and rheumatoid arthritis. The exact mechanisms of these causative agents and diseases are unknown. Lead poisoning is one reversible cause of sideroblastic anemia. It may be suggested by the appearance of RBC basophilic stippling on the peripheral smear. Elevated blood lead levels are diagnostic. Alcohol abuse may also result in disordered heme synthesis, which can be corrected by alcohol cessation or by parenteral pyridoxal phosphate in cases of continued abuse. Oral pyridoxine may be ineffective because of impaired conversion to the active form in alcoholic patients. 22

Anemia of Chronic Disease. Anemia of chronic disease is common and typically normochromic, normocytic. It is characterized by low serum iron levels, low total iron-binding capacity, and normal or elevated ferritin levels. Bone marrow is normal, but staining reveals an abnormality in the mobilization of iron from reticuloendothelial cells. This anemia can be differentiated from iron deficiency by the total iron-binding capacity, the serum ferritin level, bone marrow examination, and nonresponsiveness to a trial of iron therapy. Because the hematocrit is seldom less than 25 to 30%, therapy is not usually required. A complete search for occult blood loss is necessary during the evaluation of this diagnosis because iron deficiency may be superimposed. Disseminated cancer, chronic inflammation, uremia, and infection are common causes. 23-25

Macrocytic and Megaloblastic Anemia. In terms of the potential for a therapeutic response, the most important cause of macrocytosis is megaloblastic anemia. Megaloblastic anemia is the hematologic manifestation of a total-body alteration in DNA synthesis. The defective DNA synthesis is caused by a lack of the coenzyme forms of vitamin B₁₂ and folic acid. The deficiency appears clinically in tissues with rapid cell turnover, including hematopoietic cells and those of mucosal surfaces, particularly in the gastrointestinal tract. Hematopoietically, this deficiency is characterized by ineffective erythropoiesis and pancytopenia. Vitamin B₁₂ and folate deficiencies have different developmental histories, but the clinical result may be similar. Differentiation of folate and vitamin B₁₂ deficiencies usually depends on measured levels in the laboratory.

Folic acid, absorbed in the duodenum and jejunum, is commonly found in green vegetables, cereals, and fruit. It may be destroyed completely by cooking. The body requires approximately 100 µg/day and usually stores 6 to 20 mg. Therefore, a 2- to 4-month supply is available before megaloblastic changes occur. Causes of folate deficiency are listed in Box 119-6. Most patients with folate deficiency have either an inadequate dietary intake, such as alcoholic patients, or increased use, as in pregnancy.

Vitamin B₁₂ is found in foods of animal origin only and is not destroyed by cooking. It is absorbed in the ileum after binding to intrinsic factor. This glycoprotein factor is secreted by the parietal cells of the gastric mucosa and allows low levels of B₁₂ to be actively absorbed. The adult requirement is 1 or 2 µg/day, with a body store of 5 mg. Therefore, megaloblastic changes may take up to 4 years to develop after cessation of vitamin B₁₂ uptake. The various causes of vitamin B₁₂ deficiency are listed in Box 119-7. The most common cause is chronic malabsorption.

Megaloblastic anemia that is not responsive to folate or vitamin B₁₂ is commonly related to antimetabolites used in chemotherapy or rare inherited disorders of DNA synthesis.

Table 119-4 lists a number of the problems associated with megaloblastic anemia and their underlying pathologic states.
**Box 119-6 Causes of Folate Deficiency**

- **Inadequate Dietary Intake**
  - Poor diet or overcooked or processed food diet
  - Alcoholism

- **Inadequate Uptake**
  - Malabsorption with sprue and other chronic upper intestinal tract disorders, drugs such as phenytoin and barbiturates, or blind loop syndrome

- **Inadequate Use**
  - Metabolic block caused by drugs such as methotrexate or trimethoprim
  - Enzymatic deficiency, congenital or acquired

- **Increased Requirement**
  - Pregnancy
  - Increased RBC turnover: ineffective erythropoiesis, hemolytic anemia, chronic blood loss
  - Malignancy: lymphoproliferative disorders

- **Increased Excretion or Destruction or Dialysis**

**Box 119-7 Causes of Vitamin B\textsubscript{12} Deficiency**

- **Inadequate Dietary Intake**
  - Total vegetarianism: no eggs, milk, or cheese
  - Chronic alcoholism (rare)

- **Inadequate Absorption**
  - Absent, inadequate, or abnormal intrinsic factor, as seen in patients with pernicious gastrectomy and anemia. In the latter, autoimmune antibodies act against gastric parietal cells and intrinsic factor. Abnormal ileum, as can occur in sprue and inflammatory bowel disease

- **Inadequate Use**
  - Enzyme deficiency
  - Abnormal vitamin B\textsubscript{12}–binding protein

- **Increased Requirement by Increased Body Metabolism**

- **Increased Excretion or Destruction**

Figure 119-5. Megaloblastic anemia with macrocytic red cells and hypersegmented polymorphonuclear neutrophils. (From Hoffbrand AV, Pettit JE: Color Atlas of Clinical Hematology, 3rd ed. London, Mosby, 2000, p 61.)

A unique feature of vitamin B\textsubscript{12} deficiency is its neurologic involvement. Patients may have paresthesias in their hands and feet, decreased proprioception, or decreased vibratory sense. The insidiously developing classic neurologic complex includes loss of proprioception, weakness and spasticity of the lower extremities with altered reflexes, and variable mental changes such as depression, paranoid ideation, irritability, and forgetfulness. The latter two complaints have also been noted with folic acid deficiency. Vitamin B\textsubscript{12}–deficient patients have some of the lowest hemoglobin levels seen in any disease state.

Macrocytic anemia is suggested when the MCV is greater than 100 fL, but other criteria must be met for megaloblastosis to be considered the cause of the macrocytic anemia. On the peripheral smear, large oval red cells (macro-ovalocytes) and hypersegmented polymorphonuclear neutrophils are believed to be diagnostic (Fig. 119-5). A bone marrow aspirate may reveal morphologic changes consistent with megaloblastic erythropoiesis. Other potentially useful laboratory tests include vitamin B\textsubscript{12} and folate levels, red cell folate, and lactate dehydrogenase (LDH). Laboratory techniques, values, and interpretations are listed in Table 119-5. Once megaloblastic anemia is diagnosed and folate or vitamin B\textsubscript{12} deficiency determined, standard diagnostic regimen are followed to determine the precise origin of the deficiency.

Because one deficiency may cause gastrointestinal absorption changes that beget other deficiencies, the emergency physician may be forced to initiate therapy before the final diagnosis is made. However, a caution is given to obtain necessary laboratory specimens before pursuing this course. The usual dosage for patients with megaloblastic anemia secondary to folate deficiency is 1 mg of oral folic acid per day. Parenteral administration is generally unnecessary because most cases are due to dietary deficiency. In contrast, malabsorption is the most common cause of vitamin B\textsubscript{12} deficiency, and parenteral
therapy is initiated at 100 μg/day intramuscularly for the first 7 to 10 days. Thereafter, only monthly 100-μg doses are necessary. The response is often dramatic, with reticulocyte counts rising up to 30 to 50% and normalization of RBC, white blood cell (WBC), and platelet counts in 6 to 8 weeks. The use of vitamin B₁₂ or folate supplements in patients with undiagnosed anemia is to be discouraged. The use of routine vitamin B₁₂ injections in the elderly has decreased but is still a too common practice.²⁶,²⁷

Macrocytic anemias unrelated to megaloblastic changes are seen frequently. Liver disease, often associated with alcoholism, is the most common cause.²⁹ Macrocytic target cells may be seen on the peripheral smear in conjunction with this disorder. Hypothyroidism and hemolysis may also be manifested as macrocytic anemia. Screening tests to differentiate between megaloblastic anemia and macrocytic anemia of other causes include a peripheral smear for macro-ovalocytes, hypersegmented polymorphonuclear neutrophils, and the LDH level.²⁶,²⁸

Normochromic and Normocytic Anemias. The origin of normochromic and normocytic anemia secondary to decreased production is not as obvious as that of macrocytic and microcytic anemia because the latter give clues to their origin by alterations in RBC indices. One hematologic parameter that can aid in the diagnosis of normochromic anemia associated with hypoproduction is the corrected reticulocyte count. Reticulocytes reflect RBC production in bone marrow. They are RBCs released from bone marrow every 1 to 3 days and contain residual RNA that can be detected by supravital staining. Reticulocytes have an average MCV of 160 fL and in sufficient numbers can increase the MCV of the total erythrocyte count. The reticulocyte count is expressed as a percentage of the total RBC population and must be related (“corrected”) to the RBC count of the patient. Thus, the corrected reticulocyte count is equal to the measured percentage of reticulocytes times the patient’s hematocrit (%) divided by 45% (taken as the normal hematocrit). The normal range is 1 to 3%.

Normocytic anemia may be classified as being due to primary bone marrow involvement or a secondary marrow response to underlying disease.

Aplastic anemia is rare but may have severe manifestations. It is suspected in anemic patients with normal indices, a low reticulocyte count, and a history of exposure to certain drugs or chemicals (Table 119-6). It is related to drug or chemical exposure in 50% of cases. Viral hepatitis, radiation, and pregnancy have been associated with aplastic anemia. Another group of patients is considered to have an “autoimmune” origin.

The aplastic state may extend to all cell lines and results from destruction by immune-stimulated lymphocytes or failure of the marrow stem cell. Occasionally, only one cell line fails, as in RBC aplasia. This condition represents injury occurring at a later stage of cellular differentiation. The precise diagnosis necessitates bone marrow examination, but the causative factor may be difficult to determine.

General treatment of aplastic anemia includes removal of suspected marrow toxins from the environment, avoidance of aspirin, oral hygiene, and suppression of menses. Transfusions are given in life-threatening circumstances only. Bone marrow or peripheral blood stem cell transplantation from a histocompatible sibling can cure the bone marrow failure, with survival rates of 77 to 90% reported. However, because just 30% of patients have suitably matched sibling donors, only a small number undergo allogeneic transplantation. Immunosuppression with antithymocyte globulin, antilymphocyte globulin, and other cytotoxic chemotherapy is used in the majority of patients who are not stem cell transplantation candidates. Unrelated donors are preferred to avoid sensitization of the patient against the non-HLA antigens that are present in bone marrow from a family donor. The disease has a wide range of severity, and the overall 5-year survival rate is 30 to 40%. Given supportive therapy, up to 80% of patients with severe aplastic anemia still die. Bone marrow transplantation before blood product sensitization has resulted in an 80% 5-year survival rate. This is usually combined with immunosuppressive

therapy consisting of antilymphocyte globulin. Difficulty is still encountered in finding the correct immunologic match.29,30

Myelophthisic anemia is bone marrow failure resulting from replacement by an invading tumor, leukemia, lymphoma, or, rarely, a granuloma. A more basic defect or inhibitor may complicate the problem because the degree of anemia cannot always be correlated with the extent of bone marrow invasion. Any patient with oncologic disease may be subject to the development of this type of anemia. Useful clues are signs of extramedullary hematopoiesis, such as hepatosplenomegaly and a leukoerythroblastic peripheral smear that demonstrates immature WBCs, nucleated RBCs, and poikilocytosis (teardrop-shaped red cells) (Fig. 119-6). The final diagnosis is made by bone marrow examination. Therapy is directed at the underlying disorder.29,30

Myelofibrosis of unknown origin is the usual cause of primary bone marrow failure associated with extramedullary hematopoiesis. This myeloid metaplasia occurs in the liver and spleen and imparts a blood picture similar to that of myelophticic anemia. The diagnosis may be made by bone marrow examination. Treatment is supportive, although splenectomy or the use of alkylating agents may be necessary to treat complications of extramedullary blood cell production, such as hepatosplenomegaly.

The hypoplastic anemias of secondary origin are commonly seen as mild chronic anemias with low reticulocyte counts. They have a normal MCV and RDW. Their diagnosis is made by exclusion. Anemia of chronic disease may have microcytic or normocytic indices. It is associated with chronic inflammation (e.g., rheumatoid arthritis, chronic infections such as tuberculosis and osteomyelitis, and malignancy). Hypoendocrinism caused by hypothyroidism, hypoadrenalism, or hypopituitarism results in a hypometabolic state in which the bone marrow responds poorly to erythropoietin. Erythropoietin levels may be low. The anemia of chronic renal failure is thought to be caused by a number of factors. Decreased erythropoietin production, hemolysis, suppression by dialyzable factors, and increased blood loss caused by platelet abnormalities combine to cause mild to moderate anemia. If necessary, it may be corrected by erythropoietin replacement therapy.31

Increased Red Blood Cell Destruction

The hemolytic anemias are defined by a shortened life span of the erythrocyte. In their acute form, hemolytic anemias can be devastating and require rapid diagnosis and intervention (see Box 119-1). Fortunately, they are relatively rare in comparison to the chronic hemolytic conditions. Chronic disorders may be related to primary blood disorders (e.g., sickle cell anemia) or may be a result of other disease states (e.g., chronic renal failure). These disorders may be manifested as acute hemolytic anemia if the tenuous balance between red cell production and destruction is upset. If the patient can be demonstrated to have a normal hematocrit and reticuloocyte count at the same time, differentiation between acquired and inherited hemolytic anemia is possible.32

Clinical Features. The clinical signs and symptoms of hemolytic anemia are, in general, caused by either intravascular or extravascular processes. Although not a precise representation of the underlying pathophysiologic condition, this division assists in the differential approach in the emergency department.

Intravascular hemolysis is usually associated with an acute process and has a dramatic appearance. Large numbers of RBCs may be lysed within the circulation. Pathologically, it primarily involves the handling of released hemoglobin and a compensatory response to an acute decrease in oxygen-carrying capability. Free hemoglobin initially binds to haptoglobin and hemopexin. This complex is transported to the liver, converted to bilirubin, conjugated, and excreted. When this binding and transport system is overwhelmed, free hemoglobin may appear in the blood. Hemoglobin is a large molecule that remains in serum and may tint it pink.

In contrast, myoglobin is a small molecule that is rapidly cleared from serum. Examination of spun whole blood demonstrates clear serum in myoglobinemia, pink serum with free hemoglobin from intravascular hemolysis, and yellow serum from extravascular hemolysis with increased bilirubin production. In severe cases, the latter mechanism may also result in free hemoglobin.

The clinical appearance of intravascular hemolysis may vary from mild chronic anemia, as seen in cases of mechanical hemolysis, to prostration, fever, abdominal and back pain, and mental changes, as seen with transfusion reactions. Jaundice, brown to red urine, and oliguria associated with acute renal failure induced by the hemoglobin complex can also occur.

Extravascular hemolysis is more common and usually better tolerated. Splenic blood flow slows as RBCs travel in the sinusoids close to the reticuloendothelial system, the latter being uniquely designed for removing older or damaged cells. Primary splenic overactivity, antibody-mediated changes, or RBC membrane abnormalities may cause this normal splenic function to increase to a pathologic degree. Hemolysis may also occur within the bone marrow. As stated previously, normal erythropoiesis is ineffective 10 to 20% of the time. This percentage increases when abnormal RBCs are produced, as in thalassemia, megaloblastic anemia, or some hemolytic anemias.32,33

After hemoglobin is disassembled in the reticuloendothelial cell, globin returns to the amino acid pool, iron is transported via transferrin to the bone marrow or iron stores, and the pyrrole ring is converted to bilirubin. The unconjugated bili-
rubin circulates to the liver and is transformed. It is excreted in urine as conjugated bilirubin. The clinical picture of extravascular hemolysis is usually mild to moderate anemia, mild and intermittent jaundice, and enlargement of the spleen. The signs and symptoms vary with the severity and chronicity of the hemolysis.

Ancillary Evaluation. Once hemolysis is suspected, the history and laboratory tests have diagnostic precedence over physical examination. Important historical and physical examination points are listed in Box 119-8.32,33

Laboratory Assessment. Important diagnostic tests for hemolysis are provided in Box 119-9.

The blood smear is often more diagnostic than bone marrow examination. The typical cell seen in intravascular hemolysis is the schizocyte (Fig. 119-7). The classic cell of extravascular hemolysis is the spherocyte (Fig. 119-8). It may be seen in congenital spherocytosis but more commonly indicates splenic activity against an antibody-coated RBC membrane. An increase in macrocytes reflects the presence of younger cells associated with reticulocytosis. The specific diagnosis may be made by a blood smear, as with sickled cells or Heinz bodies in glucose-6-phosphate dehydrogenase (G6PD) deficiency.33,34

Haptoglobin binds hemoglobin on a molecule-for-molecule basis. Its absence implies saturation and degradation after binding with hemoglobin and is an early finding in hemolysis. It has a normal range of 40 to 180 mg/mL, is decreased in hepatic failure, and increases as an acute-phase reactant. After haptoglobin is bound, hemoglobin binds with hemopexin, transferrin, and albumin before circulating in its free form. Plasma free hemoglobin levels are determined in suspected cases of intravascular hemolysis. The result is considered positive if the level is greater than 40 to 50 mg/dL. Hemoglobin is excreted by the kidney and may be found as a smoky red pigment that is orthotolidine positive with no associated

**Figure 119-7.** Schizocytes (fragmented cell and nucleated red cells). (From Hoffbrand AV, Pettite JE: Color Atlas of Clinical Hematology, 3rd ed. London, Mosby, 2000, p 115.)

**Figure 119-8.** Spherocytosis. (From Hoffbrand AV, Pettite JE: Color Atlas of Clinical Hematology, 3rd ed. London, Mosby, 2000, p 115.)
RBCs. Prussian blue–staining granules of hemosiderin may be found intracellularly in renal tubule cells excreted in urine during chronic hemolytic states.34

LDH is released when the RBC is broken down peripherally or in the marrow. It is elevated in hemolytic, thalassemic, sideroblastic, and megaloblastic anemia. It may also be seen in cases of uremia, polycythemia vera, and erythroleukemia. Normal levels of LDH range from 95 to 200 IU and may be fractionated.33,34

In extravascular hemolysis, bilirubin is often delivered to the liver faster than the conjugating mechanism can handle it. Normal total levels are less than 1.5 mg/dL, and the indirect component amounts to less than 0.5 mg/dL. Conjugated or indirect bilirubin may rise as high as 4 or 5 mg/dL even with normal liver function. Higher levels connote some degree of underlying hepatic insufficiency.33,34

The direct antiglobulin (Coombs') test detects antibody or complement on human RBC membranes. It is an essential test in the evaluation of hemolysis. Approximately 90% of patients with autoimmune hemolytic anemia have a positive direct Coombs' test. The indirect test measures antibody titers in serum. The key to the direct antiglobulin test is the reagent. It contains an antihuman IgG that is produced in rabbits. This antihuman IgG in its broad-spectrum form reacts with the IgG, IgM, or C3 proteins that may coat RBCs. The reaction causes an agglutination of RBCs that is graded from 0 to 4. Agglutinating properties depend on the size of the immunoglobulin. IgM is a large antibody form that can bridge the distance between cells, cause agglutination, and fix complement. The direct antiglobulin test is limited in diagnosing IgM-mediated hemolysis. It is best in determining IgG or complement on the RBC surface. IgG is not large enough to cause agglutination, and the antihuman globulin attaches to RBC-bound IgG, which allows agglutination. C3 is detected in a similar manner. Both represent possible immunologic causes of hemolysis. This form of hemolysis is usually mediated extravascularly through the spleen because IgG is a poor initiator of the complement system. The direct antiglobulin test evaluates the RBC surface for immunologic markers. The indirect test assumes that IgG or C3 is in the serum and tests for serum antibody activity against RBCs. Positive tests for immunologic markers do not correlate agglutination activity with the severity of hemolysis.35

**Differential Diagnosis.** Hemolytic anemias may be classified as congenital or acquired, Coombs' positive or Coombs' negative, or caused by processes intrinsic or extrinsic to the cell membrane. The last method gives a useful differential classification of hemolysis (Box 119-10).

**Intrinsic Enzyme Defects.** Eighty-five to 90% of the membrane-sustaining energy production of the erythrocyte is through the anaerobic glycolytic pathway. At least eight known enzyme deficiencies are associated with this pathway. The most common is pyruvate kinase, deficiency of which is seen as deficiencies are associated with this pathway. The most

LDH is released when the RBC is broken down peripherally or in the marrow. It is elevated in hemolytic, thalassemic, sideroblastic, and megaloblastic anemia. It may also be seen in cases of uremia, polycythemia vera, and erythroleukemia. Normal levels of LDH range from 95 to 200 IU and may be fractionated.33,34

In extravascular hemolysis, bilirubin is often delivered to the liver faster than the conjugating mechanism can handle it. Normal total levels are less than 1.5 mg/dL, and the indirect component amounts to less than 0.5 mg/dL. Conjugated or indirect bilirubin may rise as high as 4 or 5 mg/dL even with normal liver function. Higher levels connote some degree of underlying hepatic insufficiency.33,34

The direct antiglobulin (Coombs') test detects antibody or complement on human RBC membranes. It is an essential test in the evaluation of hemolysis. Approximately 90% of patients with autoimmune hemolytic anemia have a positive direct Coombs' test. The indirect test measures antibody titers in serum. The key to the direct antiglobulin test is the reagent. It contains an antihuman IgG that is produced in rabbits. This antihuman IgG in its broad-spectrum form reacts with the IgG, IgM, or C3 proteins that may coat RBCs. The reaction causes an agglutination of RBCs that is graded from 0 to 4. Agglutinating properties depend on the size of the immunoglobulin. IgM is a large antibody form that can bridge the distance between cells, cause agglutination, and fix complement. The direct antiglobulin test is limited in diagnosing IgM-mediated hemolysis. It is best in determining IgG or complement on the RBC surface. IgG is not large enough to cause agglutination, and the antihuman globulin attaches to RBC-bound IgG, which allows agglutination. C3 is detected in a similar manner. Both represent possible immunologic causes of hemolysis. This form of hemolysis is usually mediated extravascularly through the spleen because IgG is a poor initiator of the complement system. The direct antiglobulin test evaluates the RBC surface for immunologic markers. The indirect test assumes that IgG or C3 is in the serum and tests for serum antibody activity against RBCs. Positive tests for immunologic markers do not correlate agglutination activity with the severity of hemolysis.35

**Differential Diagnosis.** Hemolytic anemias may be classified as congenital or acquired, Coombs' positive or Coombs' negative, or caused by processes intrinsic or extrinsic to the cell membrane. The last method gives a useful differential classification of hemolysis (Box 119-10).

**Intrinsic Enzyme Defects.** Eighty-five to 90% of the membrane-sustaining energy production of the erythrocyte is through the anaerobic glycolytic pathway. At least eight known enzyme deficiencies are associated with this pathway. The most common is pyruvate kinase, deficiency of which is seen as deficiencies are associated with this pathway. The most
The spleen sequesters these abnormal cells. Clinical sequelae range from compensated asymptomatic anemia to severe life-threatening acquired aplastic crises. The diagnosis is made by reviewing the family history, blood smear, and osmotic fragility testing. Splenectomy is the treatment of choice for patients requiring therapeutic intervention.\(^36,39\)

Paroxysmal nocturnal hemoglobinuria is a stem cell defect causing abnormal erythrocyte, neutrophil, and platelet sensitivity to complement. It is most often seen as chronic hemolytic, hemosiderinuria, leukopenia, and thrombocytopenia. The peripheral smear is normal and the direct Coombs’ test is negative. Its major complication is thrombosis, with a predilection for the hepatic vein. Normal activation of complement with the use of sucrose or acid hemolysis (the Ham test) is diagnostic. Transfusion can be a life-threatening hazard in patients with this disease because RBC lysis is caused by donor complement. Because of this danger, only washed packed cells should be used.\(^39\)

**Intrinsic Hemoglobin Abnormality.** More than 350 types of abnormal hemoglobin have been documented. Problems that may be seen include unstable hemoglobins that appear as Heinz body positive anemia, M hemoglobins that fix iron in its ferric or methemoglobin state, and hemoglobins with increased oxygen affinity that result in tissue hypoxia and erythrocytosis.

**Sickle Cell Disease.** Sickle cell disease is the most important hemoglobinopathy for the emergency physician. In hospitals serving a large African American population, it is seen on an almost daily basis. Even experienced physicians may overlook major complications, perhaps due to complacency with regard to the patients. Clinicians with less experience may fail to recognize the complexity of the disease and the many potential complications.

**Pathophysiology.** Sickle cell disease is genetically determined. An abnormal allele at the gene loci for hemoglobin β chains produces altered messenger RNA, which in turn results in replacement of glutamic acid by valine at the sixth position from the N-terminal end of the β chain. On the molecular level, this change causes an interlocking of the affected chain with adjacent hemoglobin in the deoxygenated state. This connection causes the formation of bundles of parallel rods called tactoids. These polymers grow to form a p-crystalline gel and then a crystal. This gel formation is facilitated by low pH and reduced by the presence of other hemoglobins, such as HbF. The result is a sickled cell that is less deformable, causes an increase in the viscosity and sludging tendency of blood, and is sequestered in and destroyed by the spleen and liver. These changes may occur when smaller amounts of polymer do not result in a sickled cell and are associated with a RBC membrane leak. The clinical complex of vaso-occlusive events, chronic hemolysis, thrombosis, and organ injury is derived from this pathologic process.\(^40,44\)

The globin in hemoglobin is made up of two pairs of identical polypeptide chains. In normal hemoglobin variants and most clinically significant hemoglobinopathies, the β chains are constant. The gene loci for β chains result in HbA (α\(_2\)β\(_2\)). They may have a normal allelic substitution, such as δ chains, and result in HbA\(_2\) (α\(_2\)δ\(_2\)) or an abnormal substitution as noted in HbS. Each person has two non–sex-linked gene loci for β chains, one from each parent. The alleles appearing at these loci are both expressed in the formation of RBC hemoglobin. This fact explains the basis for the various HbS syndromes. In sickle cell trait (HbAS), the patient is heterozygous and only one parent contributes the abnormal S allele. In each cell, 50% of the hemoglobin is normal HbA. Sickle disease (HbSS) is homozygous, and all hemoglobin is HbS. Because a parent may contribute alleles other than S, a wide number of variants can exist. Two clinically important S variants are sickle cell-thalassemia and sickle cell-hemoglobin C disease. Therefore, all hemoglobinopathies that cause sickling are not HbS.\(^40,41\)

In addition, HbSS is not limited to the African American population. Up to 10% of patients with various sickling disorders are not ethnically African American.\(^40,42\)

The sickle cell trait is found in 8 to 10% of African Americans. It is usually asymptomatic, although it may also be manifested as decreased urine-concentrating ability, spontaneous hematuria, and rare vaso-occlusive crises with an increased incidence of splenic infarction at high altitudes. No added risk occurs during general anesthesia. The diagnosis is usually made after sickle cell screening (Sickledex) and a characteristic result on hemoglobin electrophoresis. Genetic counseling is a useful service for these patients.\(^40,41\)

**Clinical Features.** Sickle cell disease can be a recurrent, painful, and frustrating problem for both patients and physicians. It is estimated that less than 10% of a sickle cell population are recurrent emergency department users. The patients are seen in what is considered a vaso-occlusive crisis. Preceding infection, cold exposure, and stress such as trauma are all potential precipitating factors. Many episodes are thought to be spontaneous. The painful crisis is believed to have its origin in tissue ischemia caused by increased viscosity, sludging, and microvascular obstruction as a result of irreversibly sickled cells. Sludging and vascular blockage cause stasis, deoxygenation, and local acidosis, which promote the vicious circle of continued sickling. The pain is commonly deep and aching and is most often found in the abdomen, chest, back, and extremities. The disease may mimic an acute abdomen (e.g., cholecystitis), pulmonary embolus, renal colic, or other painful problems. Neurologic complications are not uncommon and include transient ischemic attacks, cerebral infarction, spinal cord infarction, vestibular hearing problems, and hearing loss.\(^45\)

Unfortunately, HbSS may also contribute to these same problems. A directed history that relates this pain pattern to previous sickling episodes, a careful repeated physical examination, and specific organ-related laboratory tests are all the physician has to differentiate “uncomplicated” crises from a more serious pathologic condition. Children may be seen more often with skeletal crises leading to bone deformities. In these cases, osteomyelitis and bone infarct must be differentiated.\(^41,45\)

Acute chest syndrome is a leading cause of death and accounts for 25% of premature deaths associated with sickle cell disease. It is a common cause of hospitalization in sickle cell disease, second only to vaso-occlusive crisis. Patients with acute chest syndrome have fever, cough, chest pain, dyspnea, and new infiltrates on the chest radiograph. The pathophysiology of the syndrome is not well understood but suggests that it may be a specific form of acute lung injury. The injury is postulated to be related to pulmonary microvascular sludging, infarction of pulmonary parenchyma, and bone marrow fat embolization from infarcted bone. Macrovascular pulmonary embolism and infection may also have a pathogenetic role. The differential diagnosis includes pneumonia, pulmonary embolism, congestive heart failure, and adult respiratory distress syndrome. No definitive diagnosis or therapy is currently available for acute chest syndrome. Management is supportive and consists of hydration, analgesia, maintenance of adequate oxygenation and ventilation, and empirical antibiotics.\(^40,47\)

Although most of the diagnostic and therapeutic problems of sickle cell disease are related to vaso-occlusive crises, other serious complications must be anticipated. Sickle cell disease is a chronic hemolytic state with reasonably compensated hematocrit values in the 20 to 30% range and elevated reticulocyte counts. This compensated balance may be disrupted by a rare iron deficiency or, more commonly, by folate deficiency. A potentially life-threatening aplastic crisis may be seen as a
result of suppression of erythropoiesis by an acute postinfectious condition or folate deficiency. This aplastic condition is suspected when the hemoglobin level falls 2 g/dL or more from previous stable levels and the reticulocyte count remains low (<2%). Finally, children may have an acute splenic sequestration syndrome. This syndrome involves acute splenic enlargement from increased intrasplenic sickling and obstruction. The child may demonstrate lassitude and be in shock. Each of these conditions may result in a rapidly falling RBC count and progressive symptoms of anemia. Patients with HbSS are also subject to all other causes of anemia, such as hemolysis from G6PD deficiency.47 An increased susceptibility to infection is well documented with HbSS. In infancy, an increased incidence of sudden death may be related to pneumococcal sepsis and meningitis. A WBC count and blood cultures should be performed on all febrile children with sickle cell anemia. Those younger than 2 years with temperatures of 39.5°C or higher and WBC counts greater than 20,000/mm³ should be given intravenous antibiotics immediately. Adults with fever require careful evaluation and laboratory assessment, including appropriate cultures. Early institution of appropriate antibiotics is necessary in patients with a discernible source of infection. In children and adults, infection with *Staphylococcus* and *Pneumococcus* species and *Haemophilus influenzae* is particularly common. An increased incidence of *Salmonella* osteomyelitis also occurs. The origin of this related immunologic deficiency is believed to be multifactorial, with functional asplenia, poorly migrating neutrophils, and decreased opsonin production being contributors.46

Major, chronic organ damage in patients with sickle cell anemia is common. A cross section of these problems is listed in Table 119-7. These associated conditions should be quickly reviewed every time a patient with sickle cell anemia enters the emergency department. The leading causes of death in HbSS patients are cardiopulmonary disease, chronic renal failure, stroke, and infection.42,43

Diagnostically, most patients with HbSS seen in the emergency department are well-known with defined pain patterns. Because of a slow but longer growth period caused by the delayed onset of puberty, adult patients with HbSS have a youthful appearance and long, thin extremities. In a patient with suspected sickle cell disease, inquiry should be made into the family history, previous pain episodes, and symptoms relative to chronic anemia, susceptibility to infection, and ischemic organ damage. Table 119-7 suggests an outline to follow for the physical examination.

All patients should have a complete blood count performed, and current blood levels should be compared with those of previous visits. A reticulocyte count should be obtained whenever the patient’s hemoglobin level has decreased by 2 g/dL from baseline. In sickle cell disease, the typical absolute reticulocyte count is three or four times the upper limit of normal. A reticulocyte count 3% or lower than the patient’s usual value may suggest an aplastic crisis. A reticulocyte count greater than 12%, particularly if accompanied by numerous nucleated red blood cells, may indicate rapid hemolysis. Other laboratory tests are selected on the basis of potential organ complications. Unfortunately, no test is available that detects whether a patient is in a crisis. Currently, this difficult task is based on inadequate clinical grounds. In new cases, the peripheral smear may show sickled cells (Fig. 119-9), and a sickle cell screening test with Sickledex may help, particularly if drug-motivated malingering is suspected. Definitive diagnosis of sickle cell disease is aided by hemoglobin electrophoresis.31

Management. The antisickling agent hydroxyurea reduces the frequency of painful crises in adults with a history of three or more crises annually. The beneficial effects of hydroxyurea in sickle cell disease are assumed to be due to induction of hemoglobin F, but additional mechanisms may be operative.49-52 Other agents, including clotrimazole, magnesium 5-azacitidine, erythropoietin, and butyric acid, may have a future role in therapy.53-57 Bone marrow transplantation offers the only current cure for sickle cell disease. Despite survival rates greater than 90% and disease-free survival rates of 80 to 90%, the role of bone marrow transplantation in sickle cell disease remains uncertain.58,59

Current therapies, including rest, adequate nutrition, hydration, oxygenation, analgesia, transfusion, and therapy for infection, are directed toward symptomatic relief and attempts to stop the cycle of deoxygenated sickling and intravascular sludging. Most patients with sickle cell anemia are mildly dehydrated because of urine-concentrating difficulty. Fluid replacement can be oral or intravenous, and the emergency physician should be aware of the potential for congestive heart

---

failure in patients past their second decade. A satisfactory starting solution is 5% dextrose in half-normal saline begun at a rate of 150 to 200 mL/hr.

Oxygen through a nasal cannula at 2 to 4 L/min may help hypoxic patients and may be given to any patient with HbSS as a low-risk treatment modality with potential benefit. Oxygenation has been shown to decrease erythropoietin levels and the number of irreversibly sickled cells.

Analgesia is a major benefit and essential early therapy for acute sickle cell crisis. Most patients with sickle cell disease will rarely require emergency department care and only present during a severe crisis or complex illness. Because a small subgroup of patients repeatedly and frequently seek care in the emergency department, emergency department caregivers may become understandably suspicious of needs and motivations. Care protocols are advised in order to ensure rapid appropriate treatment. Many emergency physicians caring for large sickle cell patient populations have developed protocols for establishing better physician-patient rapport and lessening the chance of narcotic addiction and manipulation. The following is one protocol for severe pain: Patients are evaluated, treated with oxygen and hydration, and given intravenous morphine sulfate, 5 mg, then a constant infusion at 5 mg/hr. Another approach consists of intravenous bolus doses of morphine sulfate (0.15 mg/kg per dose up to 10 mg per dose). At 4 to 6 hours, the patient is allowed to decide whether inpatient or outpatient therapy is desired. Outpatient therapy includes 4 to 6 days of an effective oral analgesic. A 60-mg dose of oral morphine sulfate or equivalent is given 1 or 2 hours before stopping the infusion. Such a protocol may bring uniformity to the patient’s expectations for care and the physician’s decisions regarding therapy and admission. Its major disadvantage has been a tendency to treat patients automatically rather than closely considering the potential acute complications of sickle cell disease. No standard pain management exists for sickle cell disease. A variety of analgesics (nonsteroidal anti-inflammatory drugs, mixed opioid agonist-antagonists, and opiates), dosages, and timing intervals may be chosen. The most important aspect of pain management in these patients is a consistent, thorough, and attentive approach that offers true pain relief.

Blood transfusion has a well-accepted role in sickle cell anemia. Very selected use can decrease the chronic transfusion problems of antigen sensitization, iron overload, and hepatitis. Aplastic or splenic sequestration crises may necessitate transfusion. Serial hemoglobin values and reticulocyte counts must be obtained during hospitalization. Priapism may improve with transfusion, although urologic drainage procedures should be considered. Pharmacologic agents such as alpha- or beta-agonists have been used in priapism with mixed success. Exchange transfusions are recommended for patients, particularly children, with cerebrovascular accidents. Acute symptoms may be reversed and the frequency of recurrence decreased with a regulated 3- or 4-week transfusion program. The goal is to suppress reticulocytosis and decrease the HbS level to less than 25%. Rarely, transfusions are given for control of bony or visceral crises. This is not an emergency department procedure and is considered only after hematologic consultation. Prophylactic transfusions to dilute HbS levels are also recommended in pregnancy and before major surgery.

A number of other therapies are being tested for both prophylaxis and crisis management, including supplemental zinc, induced hyponatremia, gelation inhibitors, membrane-active agents, and gene manipulation. Poloxamer 188 is an artificial surfactant with hemorheologic and antithrombotic properties. Although the mechanism of action of this agent is not fully understood, it improves microvascular blood flow by reducing blood viscosity and adhesive frictional forces. In clinical trials of sickle cell patients with acute painful crisis, poloxamer reduced the total narcotic requirement, the duration of pain, and pain intensity. Careful examination, an analgesic protocol, and compassion remain the basis for management. A reason for a painful crisis should always be sought.

The general prognosis of sickle cell patients has improved because of an improvement in their care and the rapid use of antibiotics for potential infections.

Sickle Cell–β-thalassemia. Sickle cell–β-thalassemia disease is seen most commonly in people of Mediterranean descent. The severity of the disease is related to the concentration of HbS in RBCs and the decrease in MCHC. It should be considered in a patient with a low MCV and a positive sickle preparation. It is generally a milder form than homozygous sickle cell disease. HbSC disease falls between HbSS and HbS-thalassemia in terms of severity. In addition to many of the complications of HbSS, HbSC disease has an increased incidence of eye hemorrhage and pregnancy complications and may cause splenomegaly. The peripheral smear demonstrates a combination of sickled cells and normocytic target cells.

Extrinsic Alloantibodies. Alloantibodies are formed in response to foreign RBC antigens. In the case of the ABO system, these antibodies are preformed. The ABO system is one of the most important RBC wall antigens. ABO incompatibility resulting in donor cell destruction by the recipient’s alloantibodies can be a life-threatening reaction. These antibodies are IgM in nature and can act as a hemolysin, both agglutinating RBCs and fixing complement and consequently causing intravascular hemolysis.

The Rh system is another set of antigens on the RBC. This system is unique in that individuals do not have antibodies that correspond to antigens in the Rh system unless they have been sensitized by previous exposure to antigens that they lack. The antibodies produced are IgG in nature, and they accelerate extravascular destruction of RBCs by the spleen and liver. Most autoimmune antibodies are directed toward antigens in the Rh system.

Extrinsic Autoantibodies. Evaluation of autoimmune hemolysis is as complex as its origin. The major feature of autoimmune hemolysis is the production of an IgG or IgM antibody to an antigen present on the RBC membrane. Why the body responds in this manner is unknown. IgM antibodies can agglutinate, fix complement, and act as intravascular hemolysins. IgG antibodies may fix complement to the cell but do not usually complete the hemolysis process. These IgG- or C3-labeled cells undergo accelerated extravascular destruction. The direct antiglobulin test is useful in revealing these labeled cells.

Autoimmune hemolytic anemias are acquired disorders, with 40 to 50% being idiopathic. The remainder are associated with a number of diseases (Box 119-12). Classification of autoimmune hemolytic anemia is based on the optimal temperature at which the antibody reacts with the RBC membrane. Therefore, there are warm-reacting (>37°C) and cold-reacting (<37°C) antibodies.

Warm-reacting antibodies are characterized by a higher incidence in younger patients (30–60 years of age), predominance in women, variable complement fixation, and a positive direct antiglobulin test for IgG. Cold-reacting antibodies, or cold agglutinins, are seen predominantly in men and older patients (50–80 years of age) and with IgM complement fixation. They may also be found in patients with infectious mononucleosis and Mycoplasma infection, as well as lymphoma. Hemolysis may be intravascular and extravascular, and the direct antiglobulin test is positive for complement.
Clinically, a patient with immune hemolytic anemia has the signs and symptoms of anemia and, often, splenomegaly. Spherocytosis and reticulocytosis are noted in the blood smear. The direct antiglobulin test is positive in 90% of cases. The strength of the direct antiglobulin test does not correlate with the severity of the hemolysis because the Coombs’ reaction is a different antibody function than hemolysis or stimulation of reticuloendothelial sequestration. In patients with newly diagnosed, reticulocytic or severe hemolytic anemia, the emergency physician may need to institute transfusion therapy. Compatible blood may be almost impossible to find because the antibody can react with almost all donors. The most compatible donor cells in terms of the ABO and Rh systems should be transfused with the knowledge that they will be no more compatible than the patient’s own blood cells. Prednisone or its equivalent in a dose of 60 to 100 mg should be given orally or intravenously. It is believed to produce an improvement in 60% of patients with warm antibody reactions. Splenectomy and immunosuppressive therapy are also effective in treating these reactions. Cold agglutinin hemolytic anemia may be self-limited, as after infectious mononucleosis. Other forms respond well to cold avoidance, variably to immunosuppressive agents, but poorly to steroids and splenectomy. Death commonly results from uncontrolled hemolysis, the underlying primary disorder, and pulmonary embolism.55

Drug-induced hemolytic anemia may be difficult to diagnose. The emergency physician should know the drugs most often associated with this Coombs’-positive phenomenon and realize that this test is sometimes positive only in the drug’s presence. Common drugs and mechanisms of action are listed in Box 119-13.56

Extrinsic Mechanical Causes. Hemolysis may be caused by trauma to RBCs. The peripheral smear may demonstrate schizocytes or fragmented cells, which should immediately raise the suspicion of traumatic injury (see Fig. 119-7). Microangiopathic hemolytic anemia, cardiac trauma, and “march” hemoglobinemia are the most commonly encountered forms of traumatic hemolysis.

Microangiopathic hemolytic anemia is a form of microcirculatory fragmentation by threads of fibrin deposited in the arterioles. An underlying disease is inevitably present. It may be found in renal lesions such as malignant hypertension and preeclampsia, vasculitis, thrombotic thrombocytopenic purpura, disseminated intravascular coagulation, and vascular anomalies. The signs and symptoms are those of intravascular hemolysis. Treatment is directed at the causative disease. Cardiac trauma to RBCs results from increased turbulence. It may be found in patients with prosthetic valves, traumatic arteriovenous fistula, aortic stenosis, and other left-sided heart lesions. Surgical correction may be necessary. Supportive therapy with an iron supplement is usually required.

March hemoglobinemia is a form of trauma caused by breaking of intravascular RBCs by repetitive pounding. Soldiers, marathon runners, and anyone with repetitive striking against a hard surface may incur this problem. Reassurance and a change in the patient’s pattern of activity are the recommended therapy.36,67

Environmental Causes. Hemolysis may be seen in cases of severe burns, freshwater drowning, and hyperthermia. Toxic causes of hemolysis have been documented to be of animal origin, such as brown recluse spider and some snake bites; vegetable origin, such as castor beans and certain mushrooms; and mineral origin, such as copper. Certain infections are associated with hemolytic states. Malaria, Bartonella, and Clostridium sepsis are well-known causes.

Abnormal Sequestration. Hypersplenism may be caused by any disease that enlarges the spleen or stimulates the reticuloendothelial system. An unfortunate cycle can be set up in which the enlarged spleen traps more blood components and grows larger. It is usually seen as splenomegaly with pancytopenia and marrow hyperactivity. Chromium-labeled RBCs may demonstrate increased trapping in the spleen. Therapy for symptomatic or severe disease is splenectomy. Adults usually tolerate splenectomy well, but children should be approached conservatively because the risk of postsplenectomy life-threatening sepsis is increased significantly.68

### POLYCYTHEMIA

#### Definition

Polycythemia is a term commonly used for erythrocytosis (i.e., increased number of RBCs). This disorder is seen occasionally in emergency medicine but rarely in a life-threatening manner that requires emergency intervention.

#### Pathophysiology

Erythropoiesis is controlled by the kidney-produced glycoprotein hormone erythropoietin. It is activated in the liver and regulates the committed erythropoietic stem cell.
Its major stimulant is tissue hypoxia. Neoplastic dysfunction of bone marrow may also result in an elevated absolute RBC count.

The major complication of polycythemia is related to the increase in blood viscosity associated with increased RBC numbers. As the hematocrit rises past 60%, viscosity increases in an almost exponential manner. This condition increases the possibility of reduced tissue flow, thrombosis, and hemorrhage. This hazard is usually blunted to a degree by an associated increase in blood volume and some viscosity-reducing vascular dilatation.69,70

Clinical Features

The history may range from only mild headaches to a full-blown syndrome of hypervolemia (vertigo, dizziness, blurred vision, and headache), hyperviscosity (venous thrombosis), and platelet dysfunction (epistaxis, spontaneous bruising, and gastrointestinal bleeding).

On physical examination, the skin and mucous membrane manifestations of the elevated RBC count are often readily observed. Plethora, engorgement, and venous congestion are commonly noted (Fig. 119-10). Other systems to be examined include the fundus for venous congestion, the abdomen for evidence of splenomegaly, and the cardiopulmonary system for signs of congestive heart failure. Uterine, central nervous system, renal, and hepatic tumors should be sought. All are associated with secondary polycythemia. An elevated RBC count, usually greater than the hematocrit, defines the disorder. It results in a low MCV, usually related to low serum iron and iron stores. Specific laboratory testing is discussed in the section on differential diagnosis.71

Differential Diagnosis

Polycythemia is classified as apparent, primary, or secondary (Box 119-14). Apparent polycythemia is a decrease in plasma volume such as found with dehydration. The RBC volume does not exceed the upper limit of normal. Although a questionable diagnostic entity, “stress” polycythemia is the tendency for an elevated hematocrit and is found in overweight, hypertensive, and overstressed middle-aged men. Increased cigarette smoking with its associated increased carboxyhemoglobin level is considered to be partially responsible. The symptoms are minimal, and treatment is confined to moderation, weight loss, and blood pressure control. The risk of vascular occlusive complications is minimal. The hematocrit is usually less than 60% and RBC mass measurements are normal.70,71

Primary polycythemia vera is a myeloproliferative disorder found predominantly in middle-aged or older patients. It may have all the clinical components of polycythemia. Initial symptoms are reported in up to 30% of patients. The most common problems are thrombotic episodes (cerebrovascular accident, myocardial infarction, and deep vein thrombosis), bleeding, and bruising. Primary polycythemia vera is a disease that involves all cell lines—hematopoietic stem, erythroid, granulocytic, and megakaryocytic. The diagnostic criteria used by the Polycythemia Vera Study Group are listed in Box 119-15.

Polycythemia vera may be satisfactorily treated by phlebotomy as necessary. The reduced hematocrit improves some symptoms, but neither the leukocyte nor the platelet count is decreased. Maintaining the hematocrit at less than 55% is

**Figure 119-10.** Polycythemia vera. Facial plethora and conjunctival suffusion in a 40-year-old woman (Hb, 19.5 g/dL). (From Hoffbrand AV, Pettitte JE: Color Atlas of Clinical Hematology, 3rd ed. London, Mosby, 2000, p 248.)
Recommended to decrease hypervolemia and hyperviscosity. Complications necessitating additional therapy include hyperuricemia, refractory increased RBC mass, severe pruritus, excessive splenomegaly, and thrombocytopenia. Additional therapy may consist of hydroxyurea, busulfan, chlorambucil, interferon-α, anagrelide, or radioactive phosphorus ($^{32}$P). Studies suggest no improvement in long-term survival with the addition of these treatments. The natural history of the disease is that it burns out over a period of 15 to 20 years. However, myelofibrosis with myeloid metaplasia may develop in 10% of cases, acute leukemia develops with a rapid and poorly responsive downhill course. Median survival beginning from treatment to death ranges from 9 to 14 years. Studies suggest no improvement in long-term survival with the addition of these treatments. The natural history of the disease is that it burns out over a period of 15 to 20 years. However, myelofibrosis with myeloid metaplasia may develop in 10% of cases, acute leukemia develops with a rapid and poorly responsive downhill course. Median survival beginning from treatment to death ranges from 9 to 14 years.

**A number of patients with known polycythemia may be managed by outpatient phlebotomies. Any newly diagnosed or symptomatic patient should be admitted to the hospital for full evaluation.**

**WHITE BLOOD CELL DISORDERS**

The WBC count and accompanying differential are the most common laboratory tests ordered in the emergency department. It is essential that the basic physiology, pathophysiology, and clinical evaluation of WBCs be understood.

**Physiology and Pathophysiology**

The series has three morphologically indistinguishable cell types: B cells (humoral immunity), T cells (cellular immunity), and null cells. Because lymphocytes can freely leave and return to the circulation, the storage pools are less well defined. Only 5% of the total lymphocytes in the body are in the circulation. No marginal pool exists. Leukocytes primarily function extravascularly. The primary function of each series is closely integrated with the other. WBCs reach their site of action through the circulation. The rate that new cells enter the circulation is usually in equilibrium with the rate of loss in tissues.

Abnormal cell counts are due to changes in production, the marginal pool, or the rate of tissue destruction. Just as in anemia or platelet count abnormalities, the differential diagnosis of increased (leukocytosis) or decreased (leukopenia) WBC counts can be organized by processes altering production, destruction, loss, and sequestration. This chapter focuses primarily on quantitative rather than qualitative disorders.

The granulocytic and lymphocytic series are the two cell lines of WBCs. The granulocytic series is primarily involved in phagocytic activity. Its origin is the pluripotential stem cells located in the bone marrow. A subset of these cells differentiates and matures into the phagocytic cell lines, which include neutrophils, monocytes, basophils, and eosinophils. Granulocytes are maintained in a series of developmental and storage pools. The most important is the postmitotic storage pool for neutrophils, which represents 15 to 20 times the circulating population. This cell contains metamyelocytes, band neutrophils, and mature neutrophils (polymorphonuclear neutrophils). The cell can be drawn on as a ready reserve during rapid consumption of granulocytes. Circulating neutrophils are subdivided equally into the circulating neutrophil pool and the marginal pool. The latter consists of mature cells adherent to the blood vessel walls. These cells can rapidly enter the circulating pool and cause a substantial increase, even doubling, of the WBC count. This involvement does not alter the maturity pattern of the differential count. The lymphocytic series matures in lymphoid tissues located in the bone marrow, thymus, spleen, lymph nodes, and elsewhere. They are involved in the immune response against foreign substances.

**Normal Values and Influences**

One unique problem in WBC disorders is the wide variability in normal values and the multiple factors influencing them. WBC counts are generally performed automatically by using electrical impedance or optical diffraction techniques. Differential counts are commonly performed by direct examination of 100 to 500 cells with the oil immersion lens of the microscope. Automated techniques for all differential counts are...
becoming more popular, however. Normal values for the WBC count are listed in Table 119-8. The “normal” count is age dependent until childhood and may be shifted upward by exercise, gender (women), smoking, and pregnancy. Decreases in the total WBC count range of 1000 to 1200 cells/mm³ have been noted in the African American population. Laboratory errors may be due to improper sample preparation, nucleated RBCs, or platelet clumping. The blood smear differential count may also be influenced by small sample size, improper cell identification, and age group (children). Differential ranges are listed in Table 119-9. One common but easily corrected error in laboratory reporting is giving the results in terms of the percentage of cell types. Absolute counts for each cell type are more accurate and useful in assessing the risk for infection.25,26

### Abnormal Values

Because of the wide range of normal values, all abnormal WBC counts should be interpreted in the context of the patient’s condition. A careful history and physical examination, absolute cell counts, and review of the peripheral smear differential count are the starting points for determining the origins of quantitative WBC disorders.

### Leukocytosis

Most cases of leukocytosis are caused by increases in the neutrophil or lymphocyte cell lines. Neutrophil leukocytosis (neutrophilia) is an absolute neutrophil count greater than 7500 cells/mm³ and is commonly associated with infection or inflammation (Box 119-16). Because increased neutrophil destruction is associated with both these pathologic processes, bone marrow stores are drawn on, and the usual ratio of 1 band to 10 neutrophils increases. This increase is manifested as a “left shift” in the differential count and represents immature neutrophils from the postmitotic pool moving into the circulation. WBC counts can increase without a left shift or an increase in band forms by demargination of neutrophils from the vessel walls. It is often seen as a response to stress, exercise, or epinephrine. Severe stress can raise the WBC count to 18,000 to 20,000 cells/mm³.25,26

### Chronic Myeloid Leukemia

One of the myeloproliferative causes of neutrophilic leukocytosis is chronic myeloid leukemia (CML). Although it is the least common of the major leukemias (60% acute, 31% chronic lymphocytic leukemia, and 15% CML), it must be considered in neutrophilia. Patients with CML are usually older than 40 years and have WBC counts greater than 50,000 cells/mm³. The differential count shows elevated polymorphonuclear neutrophils and metamyelocytes. Less often, the basophil and eosinophil counts are increased. CML is a stem cell disorder in which the WBC count is elevated and the differential is normal. Mature and intermediate granulocytes are overproduced. Platelets may also be increased, but RBC production is down, thereby resulting in anemia. The patient often complains of fatigue, anorexia, sweating, and weight loss. Physical findings include pallor, sternal tenderness, and splenomegaly (90% of patients; Fig. 119-11). In the laboratory, decreased leucocyte alkaline phosphatase and increased vitamin B12 levels are found, which helps differentiate CML from other causes of neutrophilia. The Philadelphia chromosome (Ph) is almost constantly associated with the disease. The chronic phase of CML is treated with an alkylating agent (e.g., busulfan) or an antimetabolite (e.g., hydroxyurea). Selected patients may benefit from bone marrow transplantation.27,28

The need for urgent therapy in CML is usually related to hyperuricemia and renal injury or severe anemia and subsequent angina or heart failure. Rarely, hyperleukocytosis occurs, but the more mature, “less sticky” cells in CML do not usually cause problems unless the count exceeds 500,000 cells/mm³. A higher cell count may cause leukostasis and result in deafness, visual impairment, pulmonary ventilation-perfusion abnormalities, and priapism. Treatment involves hydration, leukapheresis, transfusion as necessary, allopurinol to prevent severe hyperuricemia, and specific chemotherapy (hydroxyurea). Late problems in the natural history of CML involve progressive loss of cell differentiation and response to therapy. The term blast crisis represents the sudden appearance of an acute form of leukemia, which is a rare substage of the evolving deterioration.27,28 The condition may occur in lymphoid or myeloid forms. Blast counts greater than 50,000 cells/mm³ may predispose the patient to the complications of leukostasis.

*Numbers in parentheses indicate the average number of cells per cubic millimeter.

Leukemia

Acute Lymphocytic Leukemia. Acute lymphocytic leukemia is most commonly diagnosed in children younger than 10 years. It is the most frequent malignancy in children younger than 15 years. The potential for leukostasis increases in acute lymphocytic leukemia when the blast count rises above 50,000 cells/mm³. Oncologic therapy is based on clinical staging and includes chemotherapy or radiation therapy. Aggressive therapy has improved childhood survival from 1 to 15 years or more. This response to treatment has not been found to the same degree in adults.80-82

Leukopenia

In adults, leukopenia is defined as an absolute blood cell count less than 4000 cells/mm³. Leukopenia is commonly associated with a reduction in one cell type, the neutrophil, and this decrease has the greatest clinical significance. The absolute neutrophil count is calculated by multiplying the WBC count by the combined percentage of band and segmented neutrophils. The absolute neutrophil count can be classified as mild (1000–1500 cells/mm³), moderate (500–1000 cells/mm³), or severe (<500 cells/mm³) according to the risk for infection. The latter is a potentially life-threatening state because the patient is markedly susceptible to overwhelming infection.
The physical signs of infection may be minimal in severe neutropenia because there are too few cells to generate a substantial inflammatory or purulent response. Neutropenia may be caused by decreased production, increased destruction, or movement of circulating neutrophils into marginal or tissue pools. Until recently, it was most often caused by a decrease in bone marrow production (Table 119-10). Autoimmune neutropenia is also becoming more commonly diagnosed because it is thought to have a role in acquired immunodeficiency syndrome.86-88

A thorough medication history must be taken in all patients found to have neutropenia. A previous history of neutropenia, a review of recent infection, and a family history are obtained. The review of systems focuses on bleeding problems, fatigue, sweats, weight loss, and autoimmune symptoms. The physical examination is directed toward sites of infection, lymphadenopathy, hepatosplenomegaly, and underlying disease. In patients with severe neutropenia and fever, a full radiologic and direct examination of commonly involved areas, such as the chest and urine, should be performed and sputum, urine, and blood cultures obtained. Basic isolation techniques, early admission, and consultation with another specialist are recommended. Specific therapies may be started after cultures and consultation are completed. A number of empirical antibiotic regimens are recommended for febrile patients with neutropenia.84,85 Human granulocyte colony-stimulating factor is often used in the setting of neutropenia, but it is best done in consultation with a hematologist.96,97 Patients with a clear reversible source or without significant clinical findings and mild to moderate levels of neutropenia may have outpatient follow-up arranged, preferably after discussion with their physician.

The WBC count has not proved to be a highly sensitive or specific test for the diagnosis of a variety of disease entities. However, in certain clinical situations, the WBC count may have utility. For example, studies evaluating the WBC count for the diagnosis of abdominal pain have found it to be a useful confirming test or helpful in selecting patients for observation. In evaluating the bacterial versus viral infectious potential in febrile children, the WBC and differential counts have demonstrated limited usefulness, except in children younger than 2 years, in whom counts greater than 15,000 cells/mm³ have an increased correlation with bacteremia.88-90

In addition to the nonspecificity of the WBC count, the differential count provides additional helpful information in less than 1% of cases. The absolute leukocyte count or the differential cannot reliably distinguish between viral and bacterial infection. The test should be viewed as having limited screening value in the acute care setting. Multiple agents and conditions increase the WBC count (Box 119-17), thus making the test less specific for infection than previously assumed.88-90

KEY CONCEPTS

- Anemia in the elderly often occurs as an exacerbation of preexisting comorbid diseases.
- Anemia of uncertain etiology should be thoroughly evaluated. If the patient has no adverse hemodynamic consequences, the evaluation can proceed on an outpatient basis.
- One of the most important but often overlooked studies in the evaluation of suspected hemolytic anemia is the peripheral blood smear.
- Patients with sickle cell disease who come to the emergency department are most commonly having a true crisis and are not simply exhibiting drug-seeking behavior.
- The white blood cell determination in the emergency department has poor sensitivity and specificity for disease.

Chapter 120 Disorders of Hemostasis

Timothy G. Janz and Glenn C. Hamilton

Perspective

Hemostasis is the process of blood clot formation and represents a coordinated response to vessel injury. It requires an orchestrated response from platelets, the clotting cascade, blood vessel endothelium, and fibrinolysis. Thrombin-stimulated clot formation and plasmin-induced clot lysis are closely related and regulated. This dynamic process is often viewed in phases: formation of a platelet plug, propagation of the coagulation cascade, formation of a clot, and fibrinolysis of the clot.

Most hemostatic abnormalities are acquired and result from drugs (e.g., aspirin or warfarin [Coumadin]), from associated disease (e.g., hepatic insufficiency), or from iatrogenic causes (e.g., multiple transfusions).

Pathophysiology

Hemostasis depends on normal function and integration of the vasculature, platelets, and the coagulation pathway.

Vasculature

Vascular integrity is maintained by a lining of nonreactive overlapping endothelial cells supported by a basement membrane, connective tissue, and smooth muscle. These cells are important in maintaining a barrier to macromolecules and, when injured, in contributing to the metabolic response and local vasoconstriction. The vascular wall is an important contributor to hemostasis.1

The endothelium contributes to both clot formation and regulation by producing substances such as von Willebrand’s factor (vWF), antithrombin III, heparin sulfate, prostacyclin, nitric oxide, and tissue factor pathway inhibitor.

Platelets

Platelets have multiple and ever-expanding roles in our understanding of hemostasis. They are complex cytoplasmic fragments released from bone marrow megakaryocytes under the control of thrombopoietin. Platelets contain lysosomes, granules, a trilaminar plasma membrane, microtubules, and a canalicular system. Granules are an important component of hemostasis and contain platelet factor 4, adhesive and aggregation glycoproteins, coagulation factors, and fibrinolytic inhibitors. Each participates in the process of coagulation. The platelet’s role is termed primary hemostasis, and it serves as the initial defense against blood loss. A fibrin clot that incorporates coagulation factors usually reinforces a platelet clot. Platelet activity is summarized in Box 120-1. Any of the steps listed may be absent, altered, or inhibited by inherited or acquired disorders.2-6

Coagulation Pathway

The coagulation pathway is a complex system of checks and balances that results in controlled formation of a fibrin clot. Coagulation factors have been given standard Roman numerals matching their order of discovery (Box 120-2).7

A simplified version of the coagulation pathway is presented in Figure 120-1. The clotting cascade is traditionally depicted as consisting of intrinsic and extrinsic pathways. The intrinsic pathway is initiated by exposure of blood to a negatively charged surface, such as a glass surface in the activated partial thromboplastin clotting time. The extrinsic pathway is activated by tissue factor exposed at the site of vessel injury or thromboplastin. Both pathways converge to activate factor X, which then activates prothrombin to thrombin. The primary physiologic event that initiates clotting is exposure of tissue factor at the injured vessel site. Tissue factor is a critical cofactor that is required for activation of factor VII. Activated factor VII activates factor X directly, as well as indirectly by activating factor IX.

Because of limited amounts of tissue factor and rapid inactivation by tissue factor pathway inhibitor, the extrinsic pathway initiates the clot process. Sustained generation of thrombin and clot formation depend on the intrinsic pathway through activation of factor IX by activated factor VII, which helps explain the bleeding problems associated with hemophilia.7,8 Intrinsic, extrinsic, and common pathways must function normally for hemostasis to occur, and each may be evaluated with laboratory tests.1,7 The clinically important groups of coagulation factors are as follows:

1. Thrombin-sensitive factors contributing to the metabolic response and local vasoconstriction: I, V, VIII, XIII
3. Sites of heparin activity: IIa, IXa, Xa (major site), XIa, platelet factor 3
Thrombin-sensitive factors are activated by thrombin and may give rise to a bleeding disorder if defective synthesis occurs. Vitamin K–sensitive factors may also cause bleeding from defective synthesis, as occurs with liver disease and warfarin anticoagulants. Heparin in combination with antithrombin III affects the coagulation pathway at multiple sites.9,12

**BOX 120-1** ROLE OF PLATELETS IN HEMOSTASIS

- Adhesion to subendothelial connective tissue: collagen, basement membrane, and noncollagenous microfibrils; serum factor VIII (von Willebrand's) permits this function; adhesion creates the initial bleeding arrest plug
- Release of adenosine diphosphate, the primary mediator and amplifier of aggregation; release of thromboxane A, another aggregator and potent vasoconstrictor; release of calcium, serotonin, epinephrine, and trace thrombin
- Platelet aggregation over the area of endothelial injury
- Stabilization of the hemostatic plug by interaction with the coagulation system:
  - Platelet factor 3, a phospholipid that helps accelerate certain steps in the coagulation system
  - Platelet factor 4, a protein that neutralizes heparin
  - Pathway initiation and acceleration by thrombin production
  - Possible secretion of active forms of coagulation proteins
  - Stimulation of limiting reactions of platelet activity

**Coagulation Control**

All the components of the coagulation reaction are necessary to prevent excessive bleeding. Hemostasis is a balance between the excessive bleeding state and thrombosis. Once coagulation is initiated, controls are necessary to prevent local or generalized thrombosis. These controls include the following:11,13-18

1. Removal and dilution of activated clotting factors via blood flow, which also mechanically opposes growth of the hemostatic plug

**BOX 120-2** COAGULATION FACTORS

I. Fibrinogens
II. Prothrombin
III. Tissue thromboplastin
IV. Calcium
V. Labile factor (proaccelerin)
VI. Not assigned
VII. Proconvertin
VIII. Antihemophilic A factor
IX. Antihemophilic B factor (plasma thromboplastin component, Christmas factor)
X. Stuart-Prower factor
XI. Plasma thromboplastin antecedent
XII. Hageman factor (contact factor)
XIII. Fibrin-stabilizing factor

**Figure 120-1.** Coagulation pathway.
2. Modulation of platelet activity by endothelial-generated nitric oxide and prostacyclin
3. Removal of activated coagulation components by the reticuloendothelial system
4. Regulation of the clotting cascade by antithrombin III, protein C, protein S, and tissue factor pathway inhibitor
5. Activation of the fibrinolytic system

**CLINICAL FEATURES**

**Out-of-Hospital Treatment**

The out-of-hospital treatment of bleeding problems presents no special concerns. Local pressure and volume repletion are the mainstays of therapy for blood loss. The out-of-hospital team must be aware that inherited coagulopathies may complicate any medical or traumatic problems and that coagulopathy can rapidly develop in critically ill patients. Patients who do not respond quickly to the usual measures of hemostasis either in the field or in the emergency department (ED) should be considered to have a potential bleeding disorder.

**History and Physical Examination**

An outline of the history and physical examination is presented in **Box 120-3**. The history alone may be useful in differentiating between platelet and coagulation factor abnormalities. Platelet disorders are usually manifested as acquired petechiae, purpura, or mucosal bleeding and are more common in women. Coagulation problems are commonly congenital, are characterized by delayed deep muscle or joint bleeding, and are seen more often in men.

**Ancillary Evaluation**

A definitive diagnosis depends on laboratory evaluation. Tests pertinent to the ED are discussed in the following sections and listed in **Box 120-4**.

**Complete Blood Count and Blood Smear**

The complete blood count (CBC) assesses the degree of anemia associated with the bleeding episode. Reductions in hemoglobin and hematocrit often lag behind the actual loss of red blood cells (RBCs) in acute hemorrhage because of a slow equilibration time. The peripheral blood smear may demonstrate schistocytes or fragmented RBCs in disseminated intravascular coagulation (DIC). Teardrop-shaped or nucleated RBCs may reflect myelophthisic disease. A characteristic white blood cell morphologic condition is seen with thrombocytopenia associated with infectious mononucleosis, folate or vitamin B12 deficiency, or leukemia.

**Platelet Count**

The platelet count may be estimated from the smear. Normally, one platelet is present per 10 to 20 RBCs. Often, the count is automated, the normal range being 150,000 to 400,000/mm³. Platelet counts less than 100,000/mm³ define thrombocytopenia. With normal platelet function, the bleeding time increases in direct relation to a decrease in the platelet count below 100,000/mm³. Levels below 20,000/mm³ may be associated with serious spontaneous hemorrhage. However, the count gives no information about the functional capability of platelets.

**COAGULATION STUDIES**

- **CBC and smear (EDTA—purple top)**
- **Platelet count (EDTA—purple top)**
- **Bleeding time**
- **Prothrombin time (citrate—blue top)**
- **Partial thromboplastin time (citrate—blue top)**
- **Other coagulation studies: fibrinogen level, thrombin time, clot solubility, factor levels, inhibitor screens**
- **As necessary: electrolytes, glucose, BUN, creatinine, type and crossmatch**

**BUN**: blood urea nitrogen; CBC, complete blood count; EDTA, ethylenediaminetetraacetic acid.

**Bleeding Time**

Bleeding time is the best test for determining both vascular integrity and platelet function that can be performed in the ED. The test is performed after making two standard incisions 1 mm deep and 1 cm long on the volar aspect of the forearm under 40 mm Hg pressure via a blood pressure cuff utilizing a template to ensure appropriate incisions. The time is mea-
sured from the incision to the moment when the blood oozing from the wound is no longer absorbed by filter paper. Some institutions have replaced the traditional bleeding time with a platelet function analyzer instrument, which is just as accurate and more convenient. A normal time is 8 minutes, a time of 8 to 10 minutes is borderline, and a time longer than 10 minutes is typically abnormal. Because of the high incidence of drug-induced platelet dysfunction, it is important to ask the patient about medications, particularly aspirin and other antiplatelet medications (e.g., clopidogrel). The test is independent of the coagulation pathways. As mentioned previously, the bleeding time is prolonged with platelet counts below 100,000/mm³, but such prolongation does not represent platelet dysfunction. However, a prolonged bleeding time associated with platelet counts greater than 100,000/mm³ suggests impaired function.

Prothrombin Time

The prothrombin time (PT) tests the factors of the extrinsic and common pathways. The patient’s anticoagulated plasma is combined with calcium and tissue factor prepared from rabbit or human brain tissue. Sensitivity to factor deficiencies depends on the source of the tissue factor. The PT detects deficiencies in fibrinogen, prothrombin, factor V, factor VII, and factor X. It is used to test the extrinsic pathway. A normal control sample is simultaneously run, and the clotting times of both are recorded. The time in seconds is usually given over the normal control time, for example, 12.5/11.5. A PT 2 seconds or more over the control time can be considered significant. Results are usually reported as the international normalized ratio (INR), which compensates for differences in sensitivity of various thromboplastin reagents to the effects of warfarin. The test is helpful in monitoring the use of coumarin anticoagulants, and the time may be prolonged in patients with liver disease and other abnormalities of vitamin K–sensitive factors.

Partial Thromboplastin Time

The partial thromboplastin time (PTT) tests the components of the intrinsic and common pathways, that is, essentially all factors but VII and XIII in the entire clotting cascade. In this test a phospholipid source and a contact-activating agent (kaolin) are added to anticoagulated citrate plasma. After an incubation period that allows factor XII to become activated, calcium is added and the clotting time is recorded. A normal control sample is run simultaneously. Normal ranges may vary, and each hospital laboratory should be checked. The average time is 25 to 29 seconds. The sensitivity of the test varies from factor to factor, but factor levels must usually be less than 40% before the PTT is prolonged. The test may be altered by clotting factor inhibitors of external origin (e.g., heparin) or internal origin (e.g., anti-VIII antibody). Inappropriately high values may occur if the plasma is too turbid or icteric. The activated PTT is most sensitive to abnormalities in the sequence of the coagulation cascade that precedes activation of factor X.

Fibrinogen

Fibrinogen is present in sufficient concentration to be measured directly. Because it is the final coagulation substrate, its level reflects the balance between production and consumption. It may be decreased by hypoproduction, as in severe liver disease, or by overconsumption, as in DIC. Low levels or altered function increase the PT, PTT, and thrombin clotting time. Because fibrinogen is an acute phase reactant, certain conditions, including malignancy, sepsis, inflammation, and pregnancy, may alter the test result.

Thrombin Time

Measurement of the thrombin clotting time bypasses the intrinsic and extrinsic pathways by directly converting fibrinogen to fibrin. It is a useful screening test for both qualitative and quantitative abnormalities of fibrinogen and inhibitors such as heparin and fibrin split products.

Clot Solubility

The result of clot solubility testing may be the only abnormality in disorders involving factor XIII deficiency and some abnormal fibrinogen. A washed clot is incubated in acetic acid or urea. If the clot is not properly cross-linked, it dissolves.

Factor Level Assays

Factor levels are determined either by bioassay, in which the ability of the sample of plasma to normalize controlled substrate-deficient plasma is evaluated, or by immunologic assay. Inhibitor screening tests reveal antibodies in plasma that prolong the normal plasma clotting time when mixed.

DIFFERENTIAL DIAGNOSIS AND MANAGEMENT

When a bleeding disorder is diagnosed or suggested, the assessment initially includes stabilization, which may necessitate volume, RBC, and coagulation factor replacement. If the disorder is known, clinical complications associated with its underlying pathophysiologic condition must be considered. If the disorder is unknown, a rapid differential diagnosis must be made. A clinically useful scheme approaches bleeding disorders in terms of three constituents: vascular integrity, platelets, and coagulation factors. This differential diagnostic approach can be further divided into inherited and acquired disorders.

Vascular Disorders

Vascular disorders have signs and symptoms similar to those of thrombocytopenic states. The inherited forms are rare. Acquired forms are usually associated with connective tissue changes or endothelial damage. The differential diagnosis of vascular disorders is listed in Box 120-5.

Platelet Disorders

General Approach

Most platelet abnormalities occur in women and are acquired. The bleeding source is usually capillary, with resultant cutaneous and mucosal petechiae or ecchymosis. Epistaxis, menorrhagia, and gastrointestinal bleeding are common initial symptoms. The bleeding is generally mild and occurs immediately after surgery or dental extractions. Petechiae and purpura may be noted on physical examination, and superficial ecchymoses may be found around a venipuncture site. Deep muscle hematomas and hemorrhhoes are not aspects of the clinical picture. The bleeding time is prolonged, and the platelet count may be low, normal, or high. The differential diagnosis of platelet disorders is listed in Box 120-6.
Thrombocytopenia

Decreased Production. Thrombocytopenia from decreased bone marrow production is usually caused by the effects of chemotherapeutic drugs, myelophthisic disease, or direct bone marrow effects of alcohol or thiazides.

Sclerosing Thrombocytopenia. Sclerosing thrombocytopenia is rare and seen primarily with hypersplenism resulting from hematologic malignancy, portal hypertension, or disorders involving increased splenic RBC destruction, such as hereditary spherocytosis or autoimmune hemolytic anemia.

Increased Destruction

Immune Thrombocytopenia. Thrombocytopenia associated with increased peripheral destruction of platelets and shortened platelet survival caused by an antiplatelet antibody is seen in a number of diseases. In most cases a cause is identifiable.

Collagen vascular diseases, particularly systemic lupus erythematosus, may cause an antiplatelet antibody–related platelet decrease. Similar associations have been noted with leukemia and lymphoma, particularly lymphocytic lymphoma. All evaluations of suggested immune thrombocytopenia should include a CBC, peripheral smear, antinuclear antibody test, and bone marrow examination. A number of drugs have been associated with thrombocytopenia of immunologic origin. Quinine and quinidine are common offenders that affect platelets through an “innocent bystander” mechanism. The platelet is coated with a drug-antibody complex, complement is fixed, and intravascular platelet lysis occurs. Because of its relatively high frequency, heparin is an important cause of drug-induced thrombocytopenia in hospitalized patients. Platelets are activated by the formation of an IgG-heparin complex.

Low-molecular-weight heparin may be associated with less thrombocytopenia than standard, unfractionated heparin; however, both forms of heparin demonstrate cross-reactivity. Heparin-induced thrombocytopenia (HIT) is a serious immune-mediated side effect associated with heparin. HIT occurs in 0.76 to 2.6% of patients receiving unfractionated heparin and in less than 1% of those receiving low-molecular-weight heparin. It usually occurs within 5 to 7 days of heparin treatment. Thrombus develops in approximately half the patients with HIT. The thrombotic complications can lead to loss of a limb in up to 20% and death in as many as 30%. The diagnosis should be suggested in the presence of absolute thrombocytopenia or a greater than 50% reduction in platelets after the initiation of heparin. The most specific diagnostic tests for HIT are serotonin release assays, heparin-induced platelet aggregation assays, and solid-phase immunoassays. Platelet-associated IgG levels are commonly elevated, but this finding is less specific or sensitive than the other diagnostic tests. More concerning to the emergency physician is delayed-onset HIT. This form of HIT occurs a median of 14 days after the initiation of heparin, but it has been reported to occur up to 40 days after starting heparin. Arterial or venous thrombosis typically develops in patients with HIT after receiving heparin. Treatment of thrombotic complications in these patients involves the use of direct thrombin inhibitors (lepirudin, argatroban), factor Xa inhibitors (fondaparinux), or heparinoids (danaparoid).

Digitoxin, sulfonamides, phenytoin, and aspirin are other problem drugs. The patient has usually ingested the medication within 24 hours. An idiopathic thrombocytopenic purpura (ITP) type of syndrome has been reported in intravenous cocaine users. Clinical trials with platelet glycoprotein IIb-IIIa antagonists suggest that intravenous glycoprotein IIb-IIIa inhibitors may confer an increased risk for associated thrombocytopenia, independent of heparin therapy. The platelet count may fall below 10,000/mm³ and be complicated by serious bleeding. Laboratory testing may confirm the presence of antibody, especially with the use of quinine and quinidine. After stopping administration of the drug, the platelet count improves slowly over a period of 3 to 7 days. A short course of

corticosteroid therapy such as prednisone in a dose of 1 mg/kg with rapid tapering may facilitate recovery.\textsuperscript{35,36}

Postinfectious immune thrombocytopenia is usually associated with viral diseases such as rubella, rubeola, and varicella. Although many cases associated with sepsis have a mechanical origin, some immune mechanisms have been demonstrated.\textsuperscript{35}

Post-transfusion thrombocytopenia is a rare disorder that causes a precipitous fall in platelets approximately 1 week after the transfusion. In 90% of cases, its origin is linked to the 98% of the population carrying a PLA1 antigen on platelets. Despite the fact that 2% of blood recipients are mismatched with respect to this antigen, it is fortunately a rare occurrence. When transfused into a PLA1 antigen-negative patient, the platelets with attached PLA1 antibodies provoke an anamnestic response, but the actual mechanism of platelet destruction remains unknown. The platelet count often falls precipitously below 10,000/mm\textsuperscript{3}, with a significant risk for major bleeding. Intracranial hemorrhage occurs in approximately 10% of such cases. Patients are usually middle-aged women with a history of pregnancy who may have previously been sensitized to the PLA1 antigen during pregnancy. Plasma exchange therapy is an effective antidote.\textsuperscript{35,37}

Idiopathic Thrombocytopenic Purpura. Autoimmune idiopathic thrombocytopenic purpura (ITP) should be considered after other causes have been excluded. ITP is associated with an IgG antiplatelet antibody that has proved difficult to detect. The two clinically important forms are acute and chronic.\textsuperscript{27,38,39}

The acute form of ITP is seen most often in children 2 to 6 years of age. A viral prodrome commonly occurs within 3 weeks of its onset. The platelet count falls, usually to less than 20,000/mm\textsuperscript{3}. The course is self-limited, with a greater than 90% rate of spontaneous remission. Morbidity and mortality rates are low, although full recovery may take several weeks. Treatment is supportive, and steroid therapy does not alter the disease course.\textsuperscript{35,39}

The more chronic form of ITP is primarily an adult disease found three times more often in women than men. The onset of chronic ITP is insidious, without a prodrome, and it is manifested as easy bruising, prolonged menses, and mucosal bleeding. The patient may have petechiae or purpura, and platelet counts between 30,000/mm\textsuperscript{3} and 100,000/mm\textsuperscript{3} are common. Bleeding complications are of unpredictable frequency and severity, although the long-term mortality rate is approximately 1%.\textsuperscript{36,39} Splenomegaly is unusual in either acute or chronic ITP.

Recently a thrombopoietin-receptor agonist, eltrombopag, has been shown to increase platelet counts in patient with relapsed or refractory ITP.\textsuperscript{36} Ertrombopag has also been used to increase platelet counts in patients with cirrhosis secondary to hepatitis C virus.\textsuperscript{41} The role that this and other thrombopoietic agents have in the standard treatment of thrombocytopenia remains to be defined. The course is one of waxing and waning severity, and spontaneous remission is rare.

Associated diseases, such as lymphoma and systemic lupus erythematosus, must be ruled out before the diagnosis can be made. Quantitative laboratory tests of antiplatelet antibody titers and short-lived hemostatic effect. Though rare, life-threatening bleeding should be treated with platelet transfusions, intravenous immune globulin (1 g/kg), and methylprednisolone (30 mg/kg IV). Otherwise, care is supportive. The use of all nonessential drugs should be stopped, particularly those that might inhibit platelet function, such as aspirin.\textsuperscript{35,38,39,42,43}

A similar pattern of thrombocytopenic purpura has been reported in sexually active homosexual men. Although the clinical findings and response to therapy mimic ITP, the mechanism is believed to be nonspecific deposition of immune complexes and complement rather than antiplatelet IgG.\textsuperscript{44}

Nonimmune Thrombocytopenia. Nonimmune platelet destruction is usually consumptive or mechanical. Consumption occurs as part of the process of intravascular coagulation, although it may be seen at sites of significant endothelial loss. Thrombotic thrombocytopenic purpura (TTP), hemolytic uremic syndrome, and vasculitis all initiate platelet destruction through endothelial damage.\textsuperscript{45,46} The most striking difference between the first two is the age at onset and the prognosis.

Thrombotic Thrombocytopenic Purpura. The pathologic state of TTP is the result of subendothelial and intraluminal deposits of fibrin and platelet aggregates in capillaries and arterioles. Hemolytic uremic syndrome is considered to be very similar to TTP; however, the former is associated with less central nervous system and more renal involvement than TTP is. Although the initiating event is unclear, prostacyclin and abnormal platelet aggregation are believed to play a central role in pathogenesis of the disease. The disease may affect patients of any age or sex, but the majority are 10 to 40 years of age and 60% of cases occur in women. Most cases of TTP are idiopathic. However, TTP can be associated with medications. Quinine is the most common drug associated with the disease. The antiplatelet drugs ticlopidine and clopidogrel, which are used to treat a variety of cardiovascular and cerebrovascular disorders, have also been associated with TTP. It is classically seen as the constellation of thrombocytopenic purpura, microangiopathic hemolytic anemia, fluctuating neurologic symptoms, renal disease, and fever, but only 40% of cases have the classic pentad.

The platelet count ranges from 10,000/mm\textsuperscript{3} to 50,000/mm\textsuperscript{3}, and generalized purpura and bleeding complaints are common. Anemia is universal, with hematocrit levels commonly less than 20%. The hemolysis may cause jaundice or pallor, and the blood smear characteristically contains numerous schistocytes and fragmented RBCs. Neurologic symptoms include stroke, seizures, paresthesias, altered levels of consciousness, and coma, all of which characteristically fluctuate in severity. The renal component varies from hematuria and proteinuria to acute renal failure. Fever is present in 90% of patients.

Untreated, the disease follows a progressive and fatal course, with 80% mortality rate 1 to 3 months after diagnosis. Therapy has included corticosteroids, splenectomy, anticoagulation, exchange transfusion, and dextran. However, plasma exchange with fresh frozen plasma (plasmapheresis) is the current treatment of choice. Over the last several years, the aggressive use of plasma exchange has reduced the mortality rate from 90 to 17%. In addition to plasma exchange, initial therapy may also include steroids such as prednisone and antiplatelet agents such as aspirin and dipyridamole (Persantine). Splenectomy, immune globulin, vincristine, and other therapies may have a role in resistant cases. With the exception of life-threatening bleeding, platelet transfusion should be avoided because platelets may cause additional thrombi in the microcirculation.\textsuperscript{45,46}

Dilutional Thrombocytopenia. Dilutional thrombocytopenia occurs in cases of massive transfusion, exchange transfusion, or extracorporeal circulation. Volume replacement with stored bank blood is platelet-poor because platelets have a life span.
of only 9 days. The number of transfusions directly correlates with the degree of thrombocytopenia. Current transfusion practice is to monitor platelet counts for every 10 U of RBCs and transfuse once the platelet count approaches 50,000/mm³.46

Thrombocytopenia

Knowledge of abnormal platelet function as a clinical disorder has grown rapidly in recent years. The drug-induced form may be one of the most commonly seen causes of abnormal bleeding.56 Defects may occur at any level of platelet function, including adhesion, release, and aggregation.

Adhesion Defects. The representative adhesion disorder is von Willebrand’s disease, which is more a factor VIII problem than a platelet deficiency. Platelets are normal in terms of their morphologic condition, number, release, and aggregation. The abnormal adhesion results not from the platelet but from an endothelium-based plasma deficiency of a factor VIII component (vWF) that permits platelet adhesion.51,52

Release Defects. Release defects include “storage pool” syndromes in which release is normal but amounts of adenosine diphosphate, calcium, and serotonin are decreased. Release defects may be congenital or acquired, as in systemic lupus erythematosus, alcoholism, or lymphoma. Drugs induce the most common release problem. Aspirin and related drugs block the enzyme cyclooxygenase, which participates in thromboxane A₂ formation. Decreased release of thromboxane A₂ results in decreased aggregation and less local vasoconstriction. Both may contribute to an increased risk of bleeding. Testing for this risk has been suggested by development of the postaspirin bleeding time as a screening test for hemorrhagic disorders. Aspirin is unique in that it permanently poisons this reaction for the life of the platelet in dosages of only 300 to 600 mg. Phenylbutazone and indomethacin affect function only while measurably circulating. A similar problem may occur in patients with uremia or dysproteinemia and as a rare inherited form.5,6,53

Aggregation Defects. Primary aggregation defects are associated with the rare recessive trait thrombasthenia. This platelet membrane abnormality may be detected by the lack of clot retraction during a 2-hour clot retraction test.20

Platelet Transfusions. Most platelet function disorders are not treated by platelet transfusion because its efficacy is questionable and alloimmunization may occur. Platelet transfusions are commonly indicated for primary bone marrow disorders (e.g., aplastic anemia or acute leukemia). Assessing the risk for spontaneous bleeding by using platelet counts is an imprecise science. Less mature platelets associated with peripheral consumption or sequestration are less likely to allow spontaneous hemorrhage than are those associated with primary bone marrow involvement. An estimate of functionality is combined with the platelet count for a better predictor of primary hemostasis potential. At counts below 50,000/mm³, a variable degree of risk exists, especially that associated with trauma, ulcers, or invasive procedures. At counts higher than 50,000/mm³, hemorrhage caused by platelet deficiency is unlikely. The transfusion threshold for platelets in trauma is not well defined and may be as high as 75,000/mm³ to 80,000/mm³. Spontaneous bleeding in the absence of surgery, trauma, or other risk factors may occur in patients with platelet counts less than 10,000/mm³.34

Thrombocytosis

Thrombocytosis may be discovered in the ED. The reactive form is considered benign. The differential diagnosis (see Box 120-6) should be considered when confronted with a platelet count higher than 600,000 to 1,000,000/mm³. The primary or autonomous state may be associated with bleeding or thrombosis. It is often an associated finding in patients with polycythemia vera, myelofibrosis, or chronic myelogenous leukemia. Suggested autonomous thrombocytosis requires a full hematologic evaluation.1,55

Disorders of the Coagulation Pathway

The coagulation system accomplishes secondary hemostasis through a complex enzymatic cascade. The clinically significant disorders have a number of characteristic features that help differentiate them from platelet disorders, including the following:18

1. The bleeding source is often an intramuscular or deep soft tissue hematoma from small arterioles.
2. The congenital form of the disease occurs predominantly in men, often as a sex-linked inheritance.
3. Bleeding may occur after surgery or trauma but is delayed in onset up to 72 hours.
4. Epistaxis, menorrhagia, and gastrointestinal sources of bleeding are rare, whereas hematuria and hemorrhage are common in severe cases.
5. The bleeding time is normal except in patients with von Willebrand’s disease.

The PT and PTT are the basic laboratory diagnostic tools for the evaluation of coagulation disorders and can be used to organize the approach to their diagnosis.18

Abnormal Prothrombin Time and Other Tests Normal

An elevated PT reflects an extrinsic pathway abnormality mediated through deficiency of factor VII. The hereditary form is caused by rare autosomal recessive gene. The acquired form is commonly seen and may be a result of vitamin K deficiency, coumarin use, or liver disease. Because factor VII has the shortest half-life (3–5 hours) of the coagulation factors, it is the first to manifest a deficiency when its active form is underproduced. The PT is a sensitive gauge of hepatic function and the efficacy of warfarin administration. INRs calculate the prothrombin ratio raised to the power of an international sensitivity index for specific thromboplastin reagents. It is recommended with most warfarin therapy that the INR be maintained between 2.0 and 3.0.56-58

Abnormal Partial Thromboplastin Time and Other Tests Normal

Two groups of inherited disorders manifest an isolated elevation in the PTT. The first group consists of the contact factors (e.g., XII [Hageman factor], prekallikrein [Fletcher factor], and high-molecular-weight kinogen). They cause a benign disorder in which the PTT is elevated but the patient has no bleeding diathesis. These deficiencies exist as isolated laboratory abnormalities, and thus they should not be invoked as a cause of the patient’s bleeding problem. They may be specifically assayed when a precise diagnosis is necessary.11,17

The second group causes significant bleeding problems resulting from deficiencies of factors within the intrinsic coagulation system. They are the most common inherited abnormalities of the entire clotting system. Deficiencies of factors VIII, IX, and XI account for 99% of inherited bleeding disorders. Patients with active life-threatening bleeding who are thought to have a congenital bleeding disorder can be sup-
ported with fresh frozen plasma, 15 mL/kg, while diagnostic studies are being performed. The risk of viral transmission of hepatitis B or C or human immunodeficiency virus must be considered.

In a patient with a prolonged PTT and a lifelong history of bleeding, the most important tests in initiating the differential diagnosis are factor VIII and factor IX assays. This test measures the ability of the patient’s plasma to correct the prolonged PTT of plasma deficient in factor VIII. This ability is compared with that of normal plasma and the result is given as a percentage of normal. The test measures the procoagulant activity of factor VIII but does not discriminate between abnormal activity resulting from abnormal factor VIII or low levels of normal factor VIII. The two forms of this deficiency are hemophilia A and von Willebrand’s disease.9

Hemophilia A. Hemophilia A is caused by a variant form of factor VIII that is present in normal levels but lacks a clot-promoting property. The incidence is 60 to 80 persons per million population. Of known cases, 70% have been found to have a sex-linked recessive nature; that is, the disease is carried on the X chromosome at location Xq28. Factor VIII circulates in plasma in very low concentration and is normally bound to vWF. The source of factor VIII production is uncertain, but the liver is thought to be a significant source because hemophilia A can be corrected by liver transplantation. A female carrier mating with a normal man would be predicted to pass the disease to half her sons. Likewise, a male hemophilic would have all normal sons and all carrier daughters. The remaining 25 to 30% of cases of the disease are believed to result from a spontaneous genetic abnormality. The familial form has a remarkable consistency of severity from generation to generation, although the degree of severity has considerable variation. This severity may be directly related to the level of factor VIII coagulant (factor VIII:C) activity. Cases with less than 1% activity are severe, with a tendency toward spontaneous bleeding. Cases with 1 to 5% activity are moderate, with rare spontaneous bleeding but increased problems with surgery or trauma. Cases with 5 to 10% activity and above are considered mild, with little risk of spontaneous bleeding but still with hazards after trauma and surgery. A number of hemophiliacs may have activity above 10% but have few problems under normal conditions. The PTT may lack sensitivity for this group because it is significantly prolonged only at factor VIII:C levels less than 40%.9,59,62

The disease is seen as a disorder of secondary hemostasis with a characteristic pattern of bleeding. Bleeding can occur anywhere, but deep muscles, joints, the urinary tract, and intracranial sites are the most common. Recurrent hemorrhages and progressive joint destruction are major causes of morbidity in hemophilia. Intracranial bleeding is the major cause of death in all age groups of hemophiliacs. Mucosal bleeding such as epistaxis and oral bleeding or menorrhagia is rare unless the disease is associated with von Willebrand’s disease or platelet inhibition, such as with aspirin use. Gastrointestinal bleeding is rare unless peptic ulcer disease is also present. Trauma is a common initiator of bleeding in all stages of severity. This potential hazard must be viewed expectantly in all hemophiliacs because late bleeding may occur, usually by 8 hours but potentially up to 1 to 5 days, and, rarely, even longer after traumatic injury.62

Management of Hemophilia A. Comprehensive management of hemophilia involves a team effort of physicians, specialized nurses, physical therapists, social workers, the patient, and the patient’s family. The therapeutic responsibility of the emergency physician consists of three areas: preparation for and identification of the problem, initial evaluation, and admission of new bleeders; replacement therapy for bleeding episodes; and anticipation of potential life threats and admission of known bleeders for observation in selected circumstances. At one time, treatment of hemophilia-associated bleeding was a relatively common emergency medicine activity, but since 1975, hemophilia home therapy has increasingly been instituted. Therefore, many hemophiliacs now come to the ED only with complicated problems or trauma-related difficulties, and most are knowledgeable about their disease.60-63

Preparation. In preparing for the problem, the emergency physician should have updated information covering disease processes and current therapy. A cooperative effort should be made between the ED and the hematology service to generate a file of known hemophiliacs in the area who are monitored at the hospital. The file should include the primary physician, diagnosis, factor VIII activity level, blood type, presence of antihemophilic factor antibodies, and time of last hospitalization. A protocol should be developed for ordering and administering factor VIII.

Replacement Therapy. The accepted therapy for hemophilia A is factor VIII replacement with cryoprecipitate or factor VIII:C concentrates. These concentrates are exposed to heat treatment or solvent-detergent mixtures to decrease transmission of hepatitis B, hepatitis C, and human immunodeficiency virus. In the past, the concentrate was made from fractionated freeze-dried antihemophilic factor and contained 250 to 1500 IU of factor VIII:C in a reconstituted volume. Factor VIII is also produced by recombinant DNA techniques and is considered to be the replacement product of choice. Recombinant-derived factor VIII is comparable to plasma-derived factor VIII in terms of characteristics and control of bleeding, but it has no discernible side effects. Factor VIII:C concentrates are commonly used in severe hemophilia and for home use. Cryoprecipitate is the cold precipitable protein fraction derived from fresh frozen plasma thawed at 1°C to 6°C. It was once the mainstay of hemophilia A therapy and may be used when noninfected factor VIII concentrates are not available.63,67

Plasma-derived replacement therapies pose some risk for hepatitis C and hepatitis B. Persistent hepatitis B surface antigen occurs in the blood of 5% of hemophiliacs, whereas the anti-B surface antigen is found in 80%. This problem has been overshadowed by the association of acquired immunodeficiency syndrome with hemophilia. The association is related to blood product use, and although the total number is low, the incidence is high—3.6 per 1000 hemophilia A patients.64,65

Therapy for a bleeding episode includes a number of considerations: the circumstances in which factor VIII is given, the dosage, the timing of maintenance, the duration of the dosage, the presence of antibodies, and the means of gauging effectiveness. Tables 120-1 and 120-2 include guidelines for the recommended treatment in a variety of circumstances. Most importantly, the emergency physician should believe patients who say that they are bleeding and institute early therapy.61,63

The response to therapy can be monitored by clinical improvement, a decreasing PTT; and, optimally, serial factor VIII:C activity levels. The infusion of 1 U of factor VIII per kilogram increases factor VIII levels by 2%. The lack of a response to factor VIII administration should raise the possibility of circulating antibodies. All hemophiliacs should be screened for the development of these antihemophilic factor antibodies when they are given in-hospital therapy or if their condition becomes refractory to home therapy. The 7 to 20% of patients in whom these IgG antibodies develop usually have a severe deficiency necessitating multiple factor VIII transfusions. The treatment may be complex, and hospitalization is

necessary. A variety of therapies have been considered, including “overwhelming” factor VIII doses, exchange plasmapheresis, immunosuppressive therapy, and the infusion of prothrombin complexes containing activated clotting factors. Other recommended therapies include porcine factor VIII, which has less cross-reactivity with the human product, and probably in the future, recombinant activated factor VIIa. Recombinant factor VIIa has been used in the treatment of some nonhemophilic patients with serious or intractable bleeding but has not proved more effective than placebo. Until more data are available, the efficacy of recombinant factor VIIa in settings outside of congenital coagulation disorders remains to be determined.63,66-71 Acquired IgG antihemophilic factor antibodies may exist in nonhemophiliac patients. They can occur in the postpartum period, as immunologic reactions to penicillin or phenytoin, and in association with systemic lupus erythematosus, rheumatoid arthritis, or inflammatory bowel disease. The diagnosis is made by the occurrence of an acquired hemophilia-like syndrome with positive antibody titers in the appropriate setting.

The “lupus anticoagulant” is unique in that it may be associated with an increased risk for thrombosis, as well as a hemorrhagic diathesis.61,72 Desmopressin acetate has been shown to increase levels of factors VIII:C and VIII:Ag in patients with hemophilia A and in some with von Willebrand’s disease. It is given intrave-

Standard Calculation
1. Patient's plasma volume = (50 mL/kg × weight in kg) × (Desired level of factor VIII [percent]) – (Present level of factor VIII [percent]) = Number of units for initial dose.
2. In emergency therapy, the present level of factor VIII is assumed to be zero.
3. One unit is the activity of the coagulation factor present in 1 mL of normal human plasma.
4. Because the half-life of factor VIII is 8–12 hr, the desired level is maintained by giving half the initial dose every 8–12 hr.
5. Cryoprecipitate is assumed to have 80–100 U of factor VIII:C per bag; factor VIII:C concentrates list the units per bottle on the label.

Effectively at 0.3 µg/kg per dose. Benefits are primarily noted in patients with mild to moderate disease and last for 4 to 6 hours.73,74

Prophylaxis. The anticipation of delayed bleeding in patients with hemophilia may necessitate admission and observation for a variety of trauma-related injuries. Candidates for prophylactic admission are patients with deep lacerations; those with soft tissue injuries in areas where the pressure from a developing hematoma could be destructive, such as in the eye, mouth, neck, back, and spinal column; and patients with a history of major trauma forces without injury. Head trauma is potentially life-threatening to hemophiliacs, and central nervous system bleeding is the major cause of death for patients in all age groups. Studies find a 3 to 15% risk of intracranial hemorrhage, yet no patient given replacement therapy within 6 hours had intracranial bleeding. It is recommended that patients who sustain head trauma but who have normal CT scans have factor VIII therapy initiated to greater than 50% activity level.75,76 All hemophiliacs with head trauma should be considered for admission and their primary physician and hematologist consulted early.

Gene therapy represents a potential development in the treatment of hemophilia. With cloning of the genes encoding factor VIII, the possibility exists for either a partial or complete cure of hemophilia. The goal of gene therapy is not to restore factor levels to normal but rather to convert from a severe to a mild phenotype and dramatically improve clinical outcomes. Early studies are encouraging. Although genetic testing and counseling are currently available, no genetic therapies for hemophilia A are available at present.61,77-80

von Willebrand's Disease. To understand von Willebrand's disease, it is helpful to review the nomenclature used to refer to factor VIII in some centers. Factor VIII has at least three activities. First is its antihemophilic, or coagulant, activity, VIII:C. All references to factor VIII in this chapter thus far have been to this activity. A second activity supports platelet adhesion and in vitro aggregation with the antibiotic ristocetin; it is called von Willebrand's factor activity, or VIII:vWF. A third component reacts with rabbit antibodies to factor VIII. It is termed the factor VIII antigen, or VIII:Ag, and relates to the measured plasma level rather than the activity of factor VIII. The antigen and cofactor activity for platelet function are structurally related.85,87 von Willebrand's disease has both decreased factor VIII:Ag levels and decreased VIII:C activity secondary to underproduction. The patient's platelets are normal in number, morphologic condition, and other functions, but in the absence of circulating factor VIII:vWF, their adhering properties are diminished. Von Willebrand's disease is the most common hereditary bleeding disorder, with an estimated prevalence of 1%. The disease occurs in 5 to 10 persons per million population as an autosomal dominant trait with a variable penetrance pattern. A rare X-linked inheritance has been described.52,81,82

Manifestations of von Willebrand's disease are usually milder and less crippling than those of hemophilia. The factor VIII:C level is in the 6 to 50% range. Bleeding sites are predominantly mucosal (e.g., epistaxis) and cutaneous. Hemarthroses are rare, but menorrhagia and gastrointestinal bleeding are common. Laboratory differentiation from hemophilia A includes an abnormal bleeding time, a decreased level of factor VIII:Ag, and abnormal platelet aggregation with ristocetin.83 In patients with severe disease, replacement therapy with factor VIII in the form of intermediate purity factor VIII concentrate is the method of choice. The initial dose is 20 to 30 IU/kg every 12 hours to keep vWF levels at 50% or to control bleeding. A unique response to the transfusion of plasma components in patients with von Willebrand's disease is the stimulation of a progressive increase in VIII:C activity that lasts 12 to 40 hours. After the initial dose, fewer units are necessary, and longer dosage schedules may be followed by a clinical response and a combination of factor VIII:C activity and serial bleeding times.

In extreme circumstances without alternatives, fresh frozen plasma may be used. A factor VIII concentrate (Humate-P) has also demonstrated sufficient VIII:vWF to treat the disease.54,84 Drug therapy with desmopressin is of benefit in patients with mild to moderately severe von Willebrand's disease. It is most useful in the common form of the disease and ideally would be given in consultation with a hematologist.85,86

Hemophilia B (Christmas Disease). Hemophilia B is a deficiency of factor IX activity. Its genetic pattern and clinical findings are indistinguishable from those of hemophilia A, but its incidence is only a fifth that of hemophilia A. Factor IX is a vitamin K–dependent glycoprotein. Its deficiency is diagnosed by a factor IX assay, usually after the factor VIII:C assay is found to be normal. The replacement schedule for factor IX is similar to that for hemophilia A, but a purified factor IX concentrate or recombinant factor IX preparation is used. The plasma prothrombin complex (factors II, VII, IX, and X) and fresh frozen plasma are also useful, but they pose a higher risk of viral transmission and venous or arterial thrombosis. The maintenance dosage schedule is increased to every 24 hours because of the longer half-life of factor IX. Clinical concerns and treatment strategies associated with hemophilia B also apply to hemophilia B.63,97,98

Similar to hemophilia A, gene testing and counseling are available. Gene therapy in animals has demonstrated promising results, and preliminary results from a human study suggest that the severity of hemophilia B can be altered and improved by gene manipulation.77,79,89,90

Miscellaneous Coagulation Disorders

A number of other disorders may be caused by a deficiency in the common coagulation pathway. An altered fibrinogen level or abnormal function is a relatively common cause. Patients with this deficiency also have an abnormal thrombin time. The inherited forms are rare. The acquired forms have been related to fibrin-blocking substances and hypofibrinogenemia, which are found most often in cases of DIC and dysfibrinogenemia associated with macroglobulinemia, multiple myeloma, and hepatoportal. In the context of emergency medicine, fibrinogen's most important role relates to its activity in DIC.
The other components of the common pathway (factors II, V, and X) have rare inherited deficiencies. The acquired forms (e.g., as with vitamin K deficiency), hepatic insufficiency (potentially all factors except VIII), and massive transfusion of stored blood (low in factors V and VIII and platelets).

**Disseminated Intravascular Coagulation.** DIC is a relatively common acquired coagulopathy. Its ubiquitous nature, multiple origins, and potentially devastating sequelae, balanced by an effective mode of therapy, make early diagnosis of this hematologic process critical. It is most often encountered in the critical care setting. Hemostasis is achieved by a fine balance between procoagulants and inhibitors and thrombus formation and lysis. The balance may be disturbed by pathologic processes that result in an out-of-control coagulation and fibrinolytic cascade within the systemic circulation. The following occurs in this abnormal clotting sequence:

1. Platelets and coagulation factors are consumed, especially fibrinogen and factors V, VIII, and XIII.
2. Thrombin is formed, and it overwhelms its inhibitor system and acts to accelerate the coagulation process and directly activate fibrinogen.
3. Fibrin is deposited in small vessels in multiple organs.
4. The fibrinolytic system by means of plasmin may lyse fibrin and impair thrombin formation.
5. Fibrin degradation products are released and affect platelet function and inhibit fibrin polymerization.
6. Coagulation inhibition levels (e.g., antithrombin III, protein C, and tissue factor pathway inhibitor) are decreased.

The clinical consequence of these processes is the life-threatening combination of a bleeding diathesis from loss of platelets and clotting factors, fibrinolysis, and fibrin degradation product interference; small vessel obstruction and tissue ischemia from fibrin deposition; and RBC injury and anemia from fibrin deposition. The condition must be considered in any patient in whom purpura, a bleeding tendency, and signs of organ injury, particularly the central nervous system and kidney, develop. This broad description is further confused clinically by the variable acuteness and intensity of intravascular clotting, the effectiveness of fibrinolysis, and other systemic manifestations of the initiating disease. 91-93

The clinical diagnosis is necessarily supported by laboratory tests. The tests recommended in Table 120-3 usually confirm the presence of DIC. Other tests (e.g., specific degradation products of fibrin, particularly D-dimer, and fibrinogen) can confirm the diagnosis. These tests are rarely available in the ED.

Two conditions that may simulate DIC are severe liver disease and primary fibrinolysis. Liver disease of this severity is usually manifested by clinical jaundice and splenomegaly. Primary fibrinolysis is a rare disorder that affects fibrinogen and fibrin but generally leaves the coagulation components (platelets, factor V, and factor VIII) in the low normal range. The paracoagulation test is negative, and the euglobulin lysis time is rapid. 92,93

When planning therapy, the emergency physician must remember that defibrination is always secondary to a serious underlying pathologic process. Once the diagnosis is confirmed, the initial treatment is focused on reversing the triggering mechanism. Many episodes of DIC are self-limited, such as in a transfusion reaction, or compensated, such as associated with a tumor mass, and do not require intervention other than support. 91,92

**PT,** prothrombin time; **PTT,** partial thromboplastin time; **RBC,** red blood cell.

Replacement therapy is usually instituted simultaneously with attempts to control the primary process. The goal is to avoid depletion of clotting factors. Treatment is partially based on which of the two major pathologic components of DIC dominates the clinical picture. If active bleeding is present, replacement therapy with platelets, coagulation factors found in fresh frozen plasma or cryoprecipitate (I, V, VIII), and blood is recommended. Selective replacement therapy can be based on the laboratory and clinical response. Retardation of bleeding, a decrease in fibrin degradation products, and a rise in platelet counts and fibrinogen levels are useful monitors. Normalization of clotting times occurs too late to be of value in monitoring. 92,93

Heparin has selective use in the treatment of DIC when fibrin deposition and thrombosis dominate the pathologic picture. Certain disease states are associated more with fibrin deposition, in which case heparin therapy should be considered. Examples include purpura fulminans, retained dead fetus before delivery, giant hemangioma, and acute promyelocytic leukemia. Heparin therapy is of little benefit in cases of meningococcemia, abruptio placenta, severe liver disease, and trauma. Low doses of heparin (300-500 U/hr) as a continuous infusion are currently recommended. Low-molecular-weight heparin may also be used instead of unfractionated heparin. Continuous monitoring of the clinical response, heparin levels, and bleeding status is necessary.

Other therapeutic agents such as antithrombin III and activated protein C have been evaluated. However, none has demonstrated an improved outcome in DIC, and only recombinant activated protein C (drotrecogin alfa) has been associated with improved outcomes in septic shock, regardless of whether DIC was present. 94-97
Chapter 120 / Disorders of Hemostasis

The goals of emergency care of patients with DIC include initial suggestion, aggressive pursuit of the diagnosis, understanding of potential life-threatening complications, and only rarely, initiation of therapy.

**DISPOSITION**

All patients with bleeding disorders of unknown cause or of a significant degree should be admitted to the hospital for further evaluation. The circumstances in which a patient with a known bleeding disorder may be discharged for home care are discussed in earlier sections on individual disease states.

**KEY CONCEPTS**

- Although hemostatic disorders are confirmed by specific patterns of laboratory tests, a careful history and focused physical examination are often the key to the diagnosis of hematologic diseases.
- The frequency of hemostatic disorders seen in the ED is unknown; however, they are likely to be more common than thought. Although classic diseases such as hemophilia and DIC are uncommon, the use of antiplatelet and anticoagulation agents is common in other disease states such as cardiovascular diseases.
- Hemophilia patients are often highly informed about their disease. Patient input should be solicited and respected, and early consultation with the patient’s hematologist is encouraged. Early treatment with replacement factor while diagnostic testing proceeds is encouraged.
- Platelet dysfunction is often equated with low platelet counts. Even though critical thrombocytopenia increases the risk of bleeding, particularly with trauma and surgery, dysfunction can occur at normal platelet counts. For example, antiplatelet therapy and renal disease can alter platelet function without reducing blood counts.

PERSPECTIVE

Cancer remains the second leading cause of death in the United States. In 2007 alone, more than 1.4 million cases were diagnosed and 559,000 people died of cancer. The most commonly diagnosed new cancer in men is prostate cancer and in women, breast cancer. The most common cause of cancer death for both sexes is lung and bronchial cancer. Worldwide, the most commonly diagnosed new cancer in men is lung and bronchial cancer and in women breast cancer. Similarly, the most common cause of cancer death worldwide in men is lung and bronchial cancer and in women, breast cancer.

Oncologic emergencies include fever and neutropenia, superior vena cava syndrome (SVCS), acute tumor lysis syndrome (HTS), hyperuricemia, hypercalcemia, neoplastic cardiac tamponade, spinal cord compression, and raised intracranial pressure (ICP). The accurate diagnosis and appropriate treatment of oncologic emergencies can improve the quality of life dramatically in patients with cancer. In addition, a reversible life-threatening emergency can occur in a patient with an underlying malignancy that is otherwise highly treatable or even curable, making identification and management of the oncologic emergency a potentially lifesaving action.

In 2003, it was estimated that the lifetime risk of developing cancer was 1:2 for men and 1:3 for women. Therefore, the emergency department (ED) physician should be well-versed in oncologic emergencies. Many factors can hinder the identification and management of oncologic emergencies in the ED (Box 121-1):

- Changing trends in cancer that have produced an increased number of ED visits secondary to cancer and its complications include:
  - More aggressive and broader use of chemotherapy regimens
  - Increasing use of bone marrow transplantation
  - More effective treatment options, increasing cure and survival rates
  - Increased number of elderly patients receiving chemotherapy
  - Increased survival for all cancers combined

FEVER

Fever in the cancer patient can be caused by inflammation, transfusions, antineoplastics, antimicrobials, and tumor necrosis. Although fever can be secondary to malignancy with a significant tumor burden, most fevers (55–70%) occurring in cancer patients have an infectious origin. Neutropenia is defined as an absolute neutrophil count (ANC) fewer than 500 cells/mm$^3$ or less than 1000 cells/mm$^3$ with predicted decrease to less than 500 cells/mm$^3$. ANC can be calculated as follows:

$$(\text{Total white blood cell [WBC] count}) \times \left(\frac{\text{Percentage of neutrophils and bands}}{100}\right) \times 6$$

The risk of infection and morbidity are increased with an ANC less than 1000/mm$^3$, and substantially higher when counts are less than 100/mm$^3$. In addition to the ANC, the risk of infection is related to the rate of development and the duration of neutropenia.

Fever in the neutropenic cancer patient should be considered a medical emergency. Prior to the era of empirical antibiotic therapy, infection accounted for almost 75% of mortality related to chemotherapy. Cancer patients with significant fever (defined by the Infectious Disease Society of America as a single oral temperature $\geq 38.3^\circ C$ [101°F] or an elevation of $38^\circ C$ [100.4°F] for at least 1 hour) and a polymorphonuclear (PMN) leukocyte count less than 500/mm$^3$ should be presumed to have an infectious origin. Antimicrobial therapy should be started immediately after appropriate cultures have been obtained.

Clinical Features

Because fever is often the first and occasionally the only sign of infection in the neutropenic cancer patient, the emergency physician must take a careful and thorough history and perform a meticulous physical examination. In the absence of PMNs, traditional markers of inflammation such as erythema, warmth, and pyuria may be absent or minimal, making it essential to search for subtle signs of inflammation. On occasion, a neutropenic patient may not present with fever despite infection. This occurs more commonly in elderly patients and patients on corticosteroids.

Many factors predispose the neutropenic patient to infection and sepsis, including prolonged bedrest, clinical deterioration, nutritional compromise, disruption of mucous membranes and skin barriers, and indwelling catheters. An undetected and untreated infection can be rapidly fatal in this population of patients. Therefore, broad-spectrum empirical antibiotic
therapy should be initiated promptly in all febrile, granulocytopenic patients (Box 121-2). Consulting with the oncologist will help categorize the risk for patients and aid selection of antibiotics based on local resistance patterns (Box 121-3).

Diagnostic Strategies

While antibiotics are being started, the patient should have a complete blood count (CBC) with differential cell count, platelet count, prothrombin time, partial thromboplastin time, blood chemistries, urinalysis, and analysis of any accessible sites suggestive of infection. Two sets of blood culture specimens should be obtained for aerobic, anaerobic, and fungal growth. If an indwelling catheter is present, at least one set of blood culture specimens should be obtained from the device lumen as well as from a peripheral vein. Obtaining a routine chest radiograph is currently the standard of care at most institutions. However, studies show that a chest radiograph is not necessary in patients with no respiratory symptoms and a normal physical examination. Urine should be sent for culture even in the absence of pyuria. However, the use of sputum culture and Gram's stain, although still recommended, has become controversial because of inconsistencies in collection and preparation that have led to false-negative and false-positive results.

Some oncologists discourage rectal temperature readings for patients with neutropenia because of the risk of tearing the rectal mucosa and establishing a potential nidus for disseminated infection. However, this has not yet become the standard of care and may vary among institutions. An indwelling nasogastric tube predisposes the neutropenic patient to sinusitis. When imaging for suggested sinusitis is required, computed tomography (CT) rather than sinus films is preferred. A lumbar puncture, preceded by head CT, is indicated when symptoms point to the central nervous system (CNS). Some authorities have recommended surveillance cultures of the stool, nose, and throat. This recommendation is not universally accepted and is generally not indicated in patients with solid tumors. Despite an intensive and comprehensive evaluation, an infectious cause is initially substantiated in only 30% of febrile, granulocytopenic patients. Nuclear scans, gallium citrate, and indium III scans do not have a place in the emergency diagnosis and treatment of these patients but may be useful in the definitive evaluation.

Differential Considerations

Overall, approximately 85% of the initial pathogens are bacterial, and of these, 60 to 70% are gram-positive pathogens. Gram-negative bacilli, particularly *Pseudomonas aeruginosa*, were the most common pathogens until the 1980s. However, the administrations of prophylactic antibiotics primarily active against gram-negative pathogens during chemotherapy, the widespread use of indwelling venous catheters and newer chemotherapy regimens have lead to an increase in gram-positive pathogens.

Staphylococcus aureus, *Staphylococcus epidermidis*, and *Streptococcus epidermidis* are the predominant gram-positive organisms. Once believed to be a contaminant, *S. epidermidis* has arisen as a major pathogen and may be resistant to antistaphylococcal penicillins and cephalosporins. *Escherichia coli*, *Pseudomonas aeruginosa*, and *Klebsiella pneumoniae* remain the most common gram-negative pathogens.

Fungal, viral, and parasitic infections are also important primary and secondary complications. Fungal infections, especially with *Candida albicans*, can be a major problem in granulocytopenic febrile patients treated with broad-spectrum antibiotics for protracted periods. Although significant institutional variation has been noted, *Histoplasma, Cryptococcus, Aspergillus*, and *Phycomyces* are additional fungal pathogens encountered in the compromised host. In contrast to patients with acquired immunodeficiency syndrome (AIDS), parasitic infections are not a common source of infection in patients with solid tumors. *Pneumocystis jiroveci* (formerly carinii), however, may be seen when corticosteroid use or hematologic malignancy has resulted in lymphocyte dysfunction. Herpes simplex, herpes varicella zoster, and cytomegalovirus are common viral pathogens. The compromised host is at risk for infection from a large number of individual pathogenic agents, thus further complicating the diagnosis and treatment of these patients.

In an attempt to prevent these infections, oncologists may initiate antimicrobial prophylaxis with trimethoprim sulfa-methoxazole (Bactrim) or quinolones for immunosuppressed patients prior to development of fever. Additionally, recombinant human granulocyte-stimulating colony-stimulating factor (G-CSF) and granulocyte macrophage CSF (GM-CSF) are used to stimulate rapid increase in granulocytes in neutropenic patients in an effort to decrease the duration and degree of neutropenia and immunosuppression.
Occasionally fever is without a source and is believed to arise from the underlying disease. However, it is impossible to differentiate using clinical and demographic factors those patients with bacteremia-induced fever from those with unexplained fever. In addition, the absence of physical findings indicative of infection does not exclude a potentially life-threatening septic event because at least 50% of septic patients lack any distinct physical findings. Despite the potential for few physical findings, a meticulous physical examination should be conducted, including the fundi (looking for Candida endophthalmitis), rectum, perineum and groin (for perirectal abscess), skin and mucous membranes (for any lesions suggesting malignancy or cellulitis), axillae, and catheters.6,11

Management

In the initial evaluation and management of the febrile cancer patient, one must take into account the particular underlying malignancy, prior use of antimicrobial therapy, and how the degree of treatment has affected the host’s immunologic compromise. For example, in acute leukemia normal circulating neutrophils and monocytes are largely replaced by blast cells, which do not function well in the phagocytizing and killing of bacterial and fungal agents. Chemotherapeutic agents and irradiation exacerbate or potentiate the underlying defect in already compromised host defenses. Corticosteroids impair granulocyte and mononuclear cell mobilization in leukemic patients. Patients with severely compromised host defenses and those in whom fever is accompanied by an increase in respiratory rate; change in mental status, agitation, or apprehensiveness; and hemodynamic instability should be urgently treated.

The optimal antimicrobial regimen should be synergistic, broad-spectrum, and bactericidal with a low potential for toxicity and chosen for efficacy against the most likely causes of systemic and rapidly progressing infection: S. aureus, E. coli, P. aeruginosa, and Klebsiella species. Traditionally, a two-drug regimen was selected because historical studies from the 1980s found that patients with gram-negative bacteremia had a higher survival rate when the isolate was sensitive to and treated with two antibiotics, compared with when the isolate was sensitive to only one of two antibiotics in the combined regimen.

In the past 10 years there has been significant advances in the antimicrobial armamentarium with development of broad-spectrum single agents such as the carbapenems (imipenem/cilastin, meropenem) and the third- to fourth-generation cephalosporins (cefazidime, cefepime). These agents when investigated as monotherapy for granulocytopenic, febrile patients have been found to be as effective as a dual-drug combination of an antipseudomonal penicillin (ticarcillin, carbenicillin, or piperacillin) plus an aminoglycoside (gentamicin or tobramycin) in clinical trials. Amikacin is generally reserved as a second-line aminoglycoside for isolates that demonstrate aminoglycoside resistance.7,10,11

Local resistance patterns should be used to guide treatment. Patients are risk-stratified and then treated accordingly. Patients with fever who appear in good condition are considered low risk. Patients with fever who have severe neutropenia, appear ill, and who are expected to have a protracted course, are high risk.13

Use of initial empirical vancomycin is included as first-line therapy at institutions where the incidence of methicillin-resistant S. aureus has been significant. Vancomycin should be included empirically in selected patients with:

- Positive blood cultures for gram-positive bacteria before final identification and susceptibility testing
- Hypotension or other evidence of cardiovascular impairment

Patients should be admitted to an isolation room if possible, but rapid movement out of a congested waiting room into a private space is the higher priority. Hand washing and reverse isolation techniques should be used.

Current recommendations for antimicrobial therapy of fever in neutropenic cancer patients include the following:2,5,8-10

- An antipseudomonal penicillin + an aminoglycoside ± vancomycin
- Cefazidime ± an aminoglycoside
- Cefazidime ± vancomycin
- Cefepime ± vancomycin
- Imipenem/cilastin
- Meropenem

**SUPERIOR VENA CAVA SYNDROME**

**Epidemiology**

SVCS is an acute or subacute process caused by the obstruction of blood flow through the superior vena cava (SVC) secondary to compression, infiltration, or thrombosis. Malignancy, most commonly lung cancer, is the most common cause of SVCS and currently accounts for 60 to 85 % of cases of SVCS.15 In fact, SVCS is often the initial presenting sign of the tumor.15

In recent years, benign causes for SVCS have gradually increased due to increasing use of intravascular devices.14 Other common nonmalignant causes include goiter, pericardial constriction, primary thrombosis, idiopathic sclerosing aortitis, tuberculous mediastinitis, fibrosing mediastinitis (histoplasmosis and methysergide treatment), arteriosclerotic or (rarely) luetic aneurysm, nephritic syndrome, and indwelling central venous catheters.16,17 In contrast to the adult population SVCS in pediatric patients is most often iatrogenic secondary to indwelling catheters, ventriculoperitoneal shunts, and complications of cardiovascular surgical procedures.

**Clinical Features**

Knowledge of the unique anatomic relationship of the SVC in the anterior superior mediastinum is crucial to understanding the clinical presentation of SVC obstruction. The SVC is easily compressed by any of its bounding contiguous structures (trachea, heart, aorta,azygos vein, and paratracheal and bronchial lymph nodes). This compression can produce a constellation of symptoms that reveal the exact site of the pathophysiologic process (Fig. 121-1). The SVC arises from the innominate veins, which in turn arise from the internal jugular and subclavian veins. The azygos vein, the last main auxiliary vessel of the SVC, drains blood from the chest wall. As a consequence of this anatomic relationship, if the SVC is blocked above or at the entrance of the azygos, blood may bypass and decompress the obstruction through the chest wall collateral vessels and rejoin the SVC via the azygos. If the obstruction falls below or at the entrance of the azygos, blood must traverse in a retrograde manner down the azygos and other chest wall veins to reach the drainage area of the inferior vena cava and subsequently cause more prominent symptoms.13 The severity of the syndrome is also related to the rate at which complete obstruction occurs. The more gradual the onset of obstruction, the longer the time for development of collateralization with less severe symptomatology.3
Because the clinical features of the SVCs are characterized by venous hypertension within the area ordinarily drained by the SVC, many of the findings are more noticeably evident in the recumbent or stooped-over position.

Early signs may include periorbital edema, conjunctival suffusion, and facial swelling, which will be most evident in the early morning hours and subside by midmorning. The most common symptom associated with SVCS is dyspnea with swelling of the face, trunk, and upper extremities observed in approximately 40% of patients. Cough, dysphagia, and chest pain are less commonly reported, each occurring in approximately 20% of patients. With increasing impedance to blood flow, the full-blown syndrome begins to manifest itself with thoracic and neck vein distention (67% and 59%, respectively), facial edema (56%), tachypnea (40%), tightness of the shirt collar (the Stoke sign), plethora of the face, edema of the upper extremities, and cyanosis.18,19

Early reports of severe SVCS or prolonged and severe SVCS were believed to lead to irreversible thrombosis and death.20,21 Important concepts have changed since these early reports. Little evidence in the current literature substantiates the notion of untreated SVC obstruction as life-threatening except when it occurs with tracheal compression. Survival in patients with SVCS depends mainly on the course of the underlying disease.16,18

SVCS can occur in conjunction with spinal cord compression (Rubin’s syndrome). Venous obstruction usually develops before the spinal cord compression, which is localized in most instances to the low cervical or upper thoracic spinal cord. This syndrome is most commonly found with malignancies of lymphoma and lung cancer. Patients with venous obstruction and back pain should be evaluated with magnetic resonance imaging (MRI) of the vertebral spine.

Ancillary Evaluation

The clinical diagnosis of SVC obstruction is mimicked by a few other clinical entities—most noteworthy of which are peri-cardial tamponade and heart failure, which can usually be excluded by physical examination, and pericardial effusion, which can be excluded by two-dimensional echocardiography. Because SVCS does not usually represent an immediately life-threatening oncologic emergency, once the clinical diagnosis is entertained, a tissue biopsy specimen should be obtained promptly. Although supportive therapy may be instituted to alleviate symptoms, definitive therapy should await the determination of histologic diagnosis because malignancy is known to be the cause of 60 to 85% of reported cases. The chest film reveals a mass in nearly 10% of patients. When superior mediastinal mass is present, 75% are on the right side, and in approximately 50% of patients the masses are combined with pulmonary lesions or hilar adenopathy.

Pleural effusion is an associated finding in approximately 20 to 25% of patients and is customarily found in the right hemithorax.14 Morbidity secondary to excessive bleeding from puncture sites has been reported rarely with venous access procedures. IV injections may be less reliable because of slowing of drug distribution. Low flow rates may result in local irritation with thrombosis or phlebitis. Venous access is preferable on the contralateral side to the obstruction.

Venography is relatively contraindicated because of its concomitant bleeding complications. Invasive diagnostic procedures, including bronchoscopy, mediastinoscopy, scalene node biopsy, and limited thoracotomy are commonly used to establish the diagnosis and extent of the disease. Once SVC obstruction is suggested, the appropriate consulting services should be contacted and plans for prompt diagnosis undertaken.19,21

Management

Historically, emergent radiation therapy was the treatment for SVCS. Currently, this is only recommended emergently for patients who present with stridor due to central airway obstruction or severe laryngeal edema. Current management uses chemotherapy because of the increased incidence of tumor
Risk Factors for Acute Tumor Lysis Syndrome

- Increased lactate dehydrogenase levels (>1500 U/L)
- Advanced disease with abdominal involvement
- Preexisting renal dysfunction
- Post-treatment renal failure
- Acidic urine
- Concentrated urine
- Preexisting volume depletion
- Young age

Clinical Features

Symptoms are related to the underlying malignancy and hyperuricemia, hyperkalemia, hyperphosphatemia, and hypocalcemia. Hyperuricemia with resultant urate nephropathy is the most commonly recognized metabolic cause of renal insufficiency.

The kidney provides the primary mechanism for excretion of uric acid, potassium, and phosphate. Rapid proliferation of tumor cells may exceed the removal rate of the respective substances, resulting in increased levels. In fact, increased quantities of these substances have been observed in patients undergoing rapid lysis of chemosensitive tumors.

The integrity of renal function is a critical factor in determining the degree of metabolic derangements. In patients with preexisting renal insufficiency, the metabolic derangements of acute tumor lysis are more likely to be severe. However, even when renal function appears normal at the start of treatment, the rapid lysis of certain tumors may overwhelm the excretory capacity of the kidney. Similar to hyperuricemia, hyperphosphatemia may also cause renal failure. A possible mechanism is precipitation of calcium phosphate within the kidney.

Hyperkalemia, along with a contributing hypocalcemia, may result in life-threatening ventricular dysrhythmias. Hypocalcemia may also cause neuromuscular instability with muscle cramps and occasionally tetany. Confusion and convulsions also have been described in case reports.

Management

In approaching a patient with potential TLS, it is “easier to stay out of trouble than get out of trouble.” The main principles of TLS management are (1) identification of high-risk patients with initiation of preventive therapy and (2) early recognition of metabolic and renal complications with prompt supportive care, including hemodialysis. Most of the complications can be readily managed when they are recognized early; however, delay in recognition and initiation of treatment of TLS can be life-threatening.

Chemotherapy should be delayed, if possible, until metabolic disturbances, especially prerenal azotemia and hyperuricemia are corrected. Initial management is aimed at the control of preexisting hyperuricemia with hydration, allopurinol, and alkalinization of the urine to a pH greater than 7. Diuretics are added if necessary, and frequent monitoring of electrolytes, calcium, and phosphorus is essential.

Hydration

Volume depletion is a major risk factor for TLS and must be corrected vigorously. Rapid intravenous (IV) hydration is the single most important intervention. Hydration not only helps correct electrolyte disturbances by diluting extracellular fluid, but it also increases intravascular volume. Increased volume enhances renal blood flow, glomerular filtration rate, and urine volume, which consequently decreases the concentration of solutes in the distal nephron and medullary microcirculation. Continuous infusion rates as high as 4 to 5 L/day yielding urine volumes of at least 2 to 3 L/day should be given unless the patient’s cardiovascular status indicates impending volume overload. Ideally, IV hydration in high risk patients should begin 24 to 48 hours prior to initiation of cancer therapy and continue for 48 to 72 hours after completion of chemotherapy.

Hyperuricemia

Allopurinol is a xanthine oxidase inhibitor and is given to reduce the conversion of nucleic acid by-products to uric acid in order to prevent urate nephropathy and subsequent oliguric
renal failure. Because allopurinol inhibits the synthesis of uric acid but has no effect on preexisting uric acid, uric acid levels usually do not fall until after 48 to 72 hours of treatment. Allopurinol usually is given orally between 300 and 600 mg/day for prophylaxis and 600 to 900 mg/day for treatment of TLS.25

Rasburicase (recombinant urate oxidase) is a newer therapy that can be used when the uric acid levels cannot be lowered sufficiently by standard approaches. This modality of treatment is rarely initiated by emergency physicians. Rasburicase is useful in cases of hyperuricemia. Humans don’t express urate oxidase; urate oxidase catalyses the conversion of poorly soluble uric acid to soluble allantoin. By converting uric acid to water-soluble metabolites, it effectively and rapidly decreases plasma and urinary uric acid levels. Unlike allopurinol, rasburicase does not increase the excretion of xanthine and other purine metabolites; therefore, it does not increase tubule crystallization of these compounds, thereby decreasing the risk of urate nephropathy.25

Most articles agree that it is wise to alkalinate the urine as a prophylactic measure against hyperuricemia, but caution is advised should hyperphosphatemia and hypocalemia develop. In patients with concomitant hyperphosphatemia, alkalization favors precipitation of calcium/phosphate complexes in the renal tubules. Furthermore, alkali therapy may aggravate manifestations of hypercalcemia such as tetany.22,26 Although alkalization increases the solubility of uric acid, the primary means of uric acid control is hydration and diuresis to maintain adequate urinary flow.24,26

The use of furosemide or mannitol for osmotic diuresis has not proven to be beneficial as front-line therapy. In fact, these modalities may contribute to uric acid or calcium phosphate precipitation in renal tubules in a volume-contracted patient. Instead, diuretics should be reserved for well-hydrated patients with insufficient diuresis, and furosemide alone should be considered for the normovolemic patient with hyperkalemia or for the patient with evidence of fluid overload.

If TLS develops and it is refractory to the previously mentioned treatments, hemodialysis should be considered as a potentially lifesaving measure. This therapy is effective in lowering uric acid, potassium, and phosphate levels, as well as in controlling uremic symptoms. See the suggested criteria for instituting hemodialysis in Box 121-5.

The prognosis is good in the absence of renal failure. If renal failure exists and hemodialysis of 5 to 7 days is necessary, the prognosis is grave. With aggressive management, the incidence of renal and metabolic complications of cytoreductive therapy may be decreased.

HYPERVERSCOSITY SYNDROME

Hyperviscosity syndrome (HVS) refers to the clinical sequelae of increased blood viscosity. Viscosity is the resistance that a liquid exhibits to the flow of one layer over another. Excessive elevations in certain paraproteins (circulating immunoglobulins) or cellular blood components (leukocytosis, erythrocytosis, and thrombocytosis) can result in elevated serum viscosity and the development of significant sludging, decreased perfusion of the microcirculation, and vascular stasis.

The outcome of these pathophysiologic events leads to the development of HVS, which requires urgent medical therapy to forestall or reverse the effects of sludging in the microcirculation of the CNS, visual system, and cardiopulmonary system.27

Pathophysiology

HVS is most commonly associated with plasma cell dyscrasias (the paraproteinemias) and is due to the large size of the excess immunoglobulin M (IgM) paraproteins in these disorders. Waldenström’s macroglobulinemia is the most common cause and accounts for about 85 to 90% of cases of HVS. Less frequently, the disease can occur in multiple myeloma (especially with myeloma proteins of the IgA and IgG3 types). Other causes include cryoglobulinemia, a benign hyperglobulinemia of the IgM-IgG type, and leukemias.25-29

The blastic phase of chronic myelogenous leukemia, chronic granulocytic leukemia, and the blast cell crisis of acute lymphoblastic and nonlymphoblastic leukemias also commonly cause HVS.27,28 Other more benign causes include leukemoid reaction, polycythemia vera, and the accumulation of abnormal hemoglobin in sickle cell disease. The incidence of HVS in Waldenström’s macroglobulinemia is found to be approximately 20%, in IgG myeloma approximately 4.2%, and in IgA myeloma as high as 25%.28

The inherent physicochemical properties of the dysproteinemias along with extremely high concentrations of these proteins seem to predispose to the development of hyperviscosity. Paradoxically, HSV also has been reported in κ-light-chain disease owing to a greater tendency to form unstable, highly polymerized circulating aggregates. The etiologic factor most responsible for HVS in the leukemias appears to be leukocytosis with WBC counts in excess of 100,000, usually accompanied by blast forms exceeding 100,000 in the peripheral smear. The clinical manifestations of HVS become most apparent when the serum viscosity relative to water is greater than 4 to 5, normal serum viscosity to water being 1.4 to 1.8.27-29

Clinical Features

A symptomatic triad of mucosal bleeding, visual disturbances, and neurologic manifestations is a classic presentation of HSV. Visual disturbances and, on occasion, visual loss may occur with retinopathy characterized by venous engorgement (e.g., “sausage-link” or “boxcar” segmentation), which is also seen in the bulbar conjunctiva, microaneurysms, hemorrhages, exudates, and occasionally papilledema. Persistent bleeding diatheses from mucosal surfaces, especially nasal mucosa, the gastrointestinal (GI) tract, and sites of minor surgery or trauma, even in the face of a normal platelet count, are common. Other clinical findings encompass myriad neurologic disturbances, including headache, dizziness, Jacksonian and generalized seizures, somnolence, lethargy, coma, auditory disturbances (including hearing loss), and hypotension. Constitutional symptoms of fatigue, anorexia, and weight loss that are non-specific early on are commonly associated with the underlying malignancy or with numerous electrolyte disturbances related to the underlying malignant process. Cardiopulmonary findings, including acute respiratory failure and hypoxemia, congestive heart failure, myocardial infarction, and valvular abnormalities have all been reported. Renal insufficiency and
failure may be a complication of the syndrome and will exacerbate existing clinical findings secondary to the expanded plasma volume.27,28

The laboratory evaluation of the patient with suggested HVS should include a coagulation study and renal, electrolyte, and differential white count profiles. Serum and urine protein electrophoresis should be done in all cases of suggested dysproteinemias; the diagnosis is supported by a large spike on the serum electrophoresis. A clue to the presence of hyperviscosity may be the inability of the laboratory to perform chemical tests on the blood because of the serum stasis and increased viscosity that jams analyzers. In multiple myeloma significant hypercalcemia may also occur, and with high M-protein fractions a factitious hypernatremia may be present. The diagnosis may be also entertained when a patient is brought to the emergency room in a stupor or coma and anemia and rouleaux formation are found on the peripheral smear.30

Because HVS is often a presenting characteristic of dysproteinemias and leukemias with blastic transformation and because a history of previously documented disease is often absent, this syndrome should be considered in patients with unexplained somnolence and coma.

Management

Emergency leukapheresis or plasmapheresis is the definitive treatment. Temporizing measures provided by the emergency physician should focus on adequate rehydration and diuresis. An immediate temporizing measure in a patient with frank coma and an established paraproteinemia is a two-unit plenectomy with replacement of the patient’s RBCs with physiologic saline.27 After plasmapheresis or leukapheresis has adequately alleviated the clinical findings, chemotherapeutic modalities can be used.

HYPERURICEMIA

Hyperuricemia is a serious and well-known consequence of certain malignant disorders, which, if recognized early, can result in a significant decrease in morbidity for the cancer patient. The major source is cell breakdown, and its major excretory pathway is via the kidneys.

Pathophysiology

The pathogenesis of hyperuricemia results from either the increased production or decreased excretion of uric acid, or both. Increased production of uric acid commonly results from accelerated generation of uric acid through purine metabolism as a result of rapid dissolution of neoplastic tissues (cell death) following chemotherapy or radiation therapy of undifferentiated lymphomas or lymphoblastic lymphomas and rapid cell proliferation and turnover with acute lymphoblastic leukemias.

In addition, hyperuricemia may be seen with multiple myeloma and occasionally with disseminated metastatic carcinoma. With massive release of precursors, uric acid levels rise precipitously and may reach levels as high as 15 to 20 mg/dL. As a result, uric acid crystals form in the highly concentrated and acidified urine of the distal tubules, intrarenal obstruction follows, and acute renal failure ensues.24,31

Chronic, moderately elevated levels of the serum uric acid may result in renal colic, obstructive uropathy, or chronic renal failure. Either uric acid renal calculi or interstitial deposits of sodium urate may develop. This situation is associated with neoplastic overproduction of uric acid precursors. Polycythemia vera, myeloid metaplasia, mast cell disease, and chronic granulocytic leukemia are often associated with this type of hyperuricemia.

Decreased excretion may be a result of underlying renal insufficiency or as a consequence of precipitation of urates in the renal tubules, parenchyma, or ureters with subsequent development of renal insufficiency and further reduction in excretion of uric acid. Three types of renal diseases are attributable to hyperuricemia: acute hyperuricemic nephropathy, uric acid nephrolithiasis, and gouty nephropathy.

Clinical Features

Hyperuricemia can occur with or without symptoms. Symptoms may be associated with the underlying malignancy. Hyperuricemia precipitated or aggravated by therapy of these diseases may occur as an isolated metabolic disturbance or may be accompanied by other manifestations of the TLS (see previous discussion on TLS). If an underlying neoplastic disease has been diagnosed, the possibility of hyperuricemia should be investigated before, during, and after treatment with chemotherapy or radiation. The hyperuricemia should be treated to prevent renal damage. In patients with urate stones and hyperuricemia, examination of the peripheral blood may provide evidence of an underlying myeloproliferative disorder. Acute oliguria following chemotherapy or radiation therapy suggests the diagnosis of hyperuricemia, and the uric acid level in the blood often far exceeds that associated with acute renal failure.

A number of benign diseases are associated with hyperuricemia that may coexist with neoplasia. These include hereditary gout, hyperparathyroidism, psoriasis, sarcoidosis, and renal failure of any cause. The long-term administration of certain drugs may lead to elevation of the serum uric acid level. Various diuretics, including thiazides and furosemide, are important examples.24,32 From a therapeutic standpoint, however, the finding of hyperuricemia obviates the importance of the primary cause; the therapy is the same.

Management

When possible, hyperuricemia should be treated before chemotherapy or radiation therapy, especially with bulky tumors or if the serum uric acid level is borderline or increased. If a uric acid elevation of more than 9 mg/dL is found, allopurinol, fluids, and alkalinization of the urine should be initiated. If possible, this regimen should be started a day or two before the initiation of chemotherapy or radiation treatment.

Patients with histories of gouty arthritis should also receive colchicine (0.6 mg orally twice a day) to avoid the acute attacks that can be associated with allopurinol administration. Patients should be kept well hydrated. In patients with acute distal tubular uric acid obstruction, treatment includes the administration of allopurinol, together with the fluid and electrolyte management used in other forms of acute renal failure.

If hyperuricemia is secondary to malignancy, cytolytic therapy should be stopped. Allopurinol in dosages of 300 to 600 mg/day usually causes a decrease in the serum uric acid level in approximately 3 days, so its administration should be started 2 or 3 days before cytolytic therapy, if time permits. Hydration is vital in maintaining a urine output above 2 L/day. Again, rasburicase (recombinant urate oxidase) is a newer therapy that can be used when the uric acid levels cannot be lowered sufficiently by standard approaches (see previous discussion on TLS).

Alkalinization to keep the urine pH above 7 can be accomplished by administering sodium bicarbonate (9–12 g/day). Diuretics are to be used as needed. Acetazolamide (Diamox)
Hypercalcemia occurs in approximately 20 to 40% of cancer patients and is the most common life-threatening metabolic disorder associated with cancer. It affects multiple organ systems and induces a variety of pathophysiologic events that may be more immediate threats to life than the cancer itself. For the purpose of this discussion, we discuss nonparathyroid causes of hypercalcemia, which is associated with malignancy.

Pathophysiology

Two mechanisms have been proposed to explain the development of hypercalcemia associated with malignancy. The first mechanism involves patients with metastatic bone involvement. This hypercalcemia is most likely associated with the release of calcium and phosphate caused by associated increased osteoclastic activity within the bone. The second mechanism involves those patients with no bone disease. A variety of tumor-produced hormone-like substances have been associated with the development of hypercalcemia, including parathyroid hormone, prostaglandins, and peptides, all of which affect bone turnover.

Hypercalcemia is a common feature of many malignancies but most often complicates cancer of the breast, lung, head, and neck, as well as multiple myeloma and leukemia. Bony metastases are not a prerequisite for hypercalcemia and when present do not necessarily cause hypercalcemia. In patients who are hypercalcemic from squamous cell lung cancer, only one in six has bone metastases. In small-cell lung carcinoma; hypercalcemia is almost never seen, despite the presence of bone marrow metastases in 20 to 50% of cases. A complex interaction of various substances (parathyroid hormone, prostaglandins, peptides, steroids, osteoclastic factors) appears to result in both increased bone synthesis and degradation. The exception is multiple myeloma, in which bone destruction is accompanied by minimal bone synthesis. Other entities that cause hypercalcemia are listed in Box 121-6.

Rarer still are factitious hypercalcemia, idiopathic hypercalcemia of infancy (with elfin facies), familial hypocalciuric hypercalcemia, and hypercalcemia from pheochromocytoma or peristitis.

Clinical Features

The development of symptoms of hypercalcemia is nonspecific. There is little correlation between serum calcium levels and the presence and severity of symptoms. Acute hypercalcemia results in marked CNS effects ranging from personality changes (depression, paranoia, lethargy, somnolence) to coma. With chronic hypercalcemia, symptoms include a history of anorexia, nausea, vomiting, constipation, polyuria, polydipsia, and memory loss. The signs, symptoms, and complications of hypercalcemia are summarized in Box 121-7.

In patients with carcinoma, any of these symptoms should suggest the diagnosis of hypercalcemia, but the emergency physician should be particularly alert to the possibility of hypercalcemia in any cancer patient with lethargy or a change in mental status. Many may also have electrolyte abnormalities such as hypokalemia and dehydration. Thus evaluation of serum electrolytes should accompany the measurement of serum calcium, phosphorus, albumin, and alkaline phosphate. In general, a serum calcium level above 14 mg/dL constitutes a medical emergency. In chronic hypercalcemia, one may see patients with blood calcium levels as high as 15 mg/dL with only mild symptoms. With an acute onset, one can see patients comatose at a level of only 12 to 13 mg/dL.

Many benign conditions can result in hypercalcemia. The most common are hyperparathyroidism and Paget's disease of bone. Clinical features include a long history of hypercalcemia symptoms, particularly renal stones. Chronic changes on bone films, such as subperiosteal reaction and cysts or a "ground-glass" appearance of the skull, suggest hyperparathyroidism. Diagnosis of Paget's disease rests in biopsy results. Vitamin D excess, milk-alkali syndrome, and adrenal insufficiency are other common causes in the differential diagnosis of hypercalcemia.

The acute onset of severe hypercalcemia or chronic exposure of the renal tubules to elevated calcium levels may reduce
the glomerular filtration rate and renal blood flow, resulting in acute renal failure.\textsuperscript{24}

**Management**

The therapeutic modalities used in the treatment of hypercalcemia are numerous, but they should always be used in conjunction with therapy of the underlying malignant disease. The exception to this is breast cancer, when hormone therapy should be stopped until hypercalcemia is regulated.

The treatment depends on the clinical status of the patient and on the calcium level in the blood, but the general principles of treatment include treating the cancer when possible, encouraging ambulation, correcting dehydration, increasing urinary calcium excretion; inhibiting osteoclastic activity (calcium removal from bone) and reducing calcium intake.

If serum calcium levels are below 14 mg/dL, oral hydration and ambulation may suffice. Normal saline solution can be administered if the oral intake is not sufficient. If the serum phosphate level is not elevated, oral phosphates may be used cautiously. Phosphosoda (5 mL by mouth, two or three times daily) is usually tolerated with mild to no diarrhea. IV phosphates are able to effectively lower the serum calcium level through precipitation of inorganic calcium phosphate salts in bone. This modality of treatment is usually not recommended, however, and if needed, it should only be done in consultation with a nephrologist or oncologist in view of their serious complications, which include widespread visceral calcifications, shock, and renal failure. This agent is usually reserved for hypercalcemia unresponsive to other agents.

Mithramycin (given as 25 μg/kg IM once every 4 to 5 days) is not generally part of the initial emergency management of hypercalcemia and has been supplanted in most cases by the bisphosphonates.

Prednisone (60–80 mg) or other corticosteroids may be effective within a few days to a week. This drug is more useful for long-term treatment than for acute control. Corticosteroids are particularly valuable in breast carcinoma, myeloma, and lymphoma. They should not be initiated without oncologic consultation because they are chemotherapeutic agents for these malignancies.

If the serum calcium level is greater than 14 mg/dL or significant symptoms are present, a more vigorous management should be undertaken. Continuous cardiac monitoring in the ED is necessary and central venous or pulmonary artery pressure monitoring may be required.

Saline rehydration and diuresis stimulates renal tubular excretion of calcium and is the most important initial component of the emergency management of hypercalcemia. Dehydration should be corrected within 1 to 2 hours with normal saline solution. When urine flow is adequate, furosemide (40–60 mg IV) may be given to increase excretion of calcium. Although the calciuric effect of furosemide is modest, it is also useful in preventing fluid overload in patients predisposed to cardiac failure. Careful attention to fluid input and output to ensure that the patient remains euolemic is necessary.

Calcitonin is a naturally occurring hormone that inhibits bone resorption and increased excretion of calcium. Calcitonin may be effective in doses of 4 to 8 IU/kg IM/SC. This treatment, although relatively safe when renal function is normal, is not generally part of the initial emergency management of hypercalcemia.

Fifty percent of hypercalcemic cancer patients also have hypokalemia. Serum potassium levels should be monitored every 4 hours and potassium chloride (20–40 mEq IV or PO) supplemented as necessary to prevent severe hypokalemia.\textsuperscript{24,31,33,35}

In the past 5 years following approval by the Food and Drug Administration, bisphosphonates have become the treatment of choice for management of cancer-induced hypercalcemia supplanting all other pharmacologic approaches except corticosteroids. Bisphosphonates act by binding to hydroxyapatite in bone and thereby inhibiting the dissolution of crystals. These agents prevent osteoclast attachment to bone matrix and interfere with osteoclast recruitment without inhibiting bone formation and mineralization.

Several agents are now available, including clodronate, pamidronate, and ibandronate, with other more potent bisphosphonates in development. Pamidronate (90 mg, given as an infusion over 4–24 hr) effectively and safely achieves normocalcemia within a few days (mean 4 days) in over 90% of patients.\textsuperscript{32,35}

### NEOPLASTIC CARDIAC TAMponade

Although cardiac tamponade resulting from neoplasm is uncommon, it can occur abruptly and result in death if not treated quickly. In most cases neoplastic cardiac tamponade is observed in patients with a previous diagnosis of cancer, typically at late stages of the disease. It is rarely seen as the initial manifestation of an extracardiac malignancy.

The decompensated state of cardiac function comes from a marked rise in intrapericardial pressure caused by accumulation of fluid within the pericardial sac resulting from malignancy or from pericardial thickening with scar formation, which results in a thick constrictive neoplastic encasement. This condition, if not recognized and decompressed promptly, can lead to circulatory compromise and death. Signs and symptoms are partially affected by the rapidity of development. In the era prior to diagnostic ultrasound this medical/oncologic emergency was often unrecognized. In one early series prior to the advent of ultrasound, the diagnosis was missed by the first physician in 11 of 17 patients and a number of times was missed by more than a single examiner.\textsuperscript{37}

In most instances, pericardial effusion is accompanied by signs and symptoms that presage the development of the clinical picture of tamponade, including dyspnea, apprehension, anxiety, and chest pain. In rare instances, tamponade may be the first manifestation of the malignancy, solid tumor, or leukemia. Any patient in the ED with a history of cancer, shortness of breath, and hypotension should be suspected of having pericardial tamponade. The diagnoses of pulmonary embolism, congestive heart failure, and anxiety can be mistakenly made in this setting.

**Etiology**

The most common cause of neoplastic pericardial tamponade is malignant pericardial effusion, often associated with postradiation pericarditis, fibrosis, and effusion. Only rarely does a tumor or radiation fibrosis cause a neoplastic constrictive pericarditis with resultant tamponade. In most reported cases, cardiac tamponade represents a clinical progression of neoplastic or postirradiation pericarditis.

Neoplastic pericarditis can result from any number of benign, malignant, primary, or secondary tumors of the pericardium or mediastinum.\textsuperscript{38-40} The most common benign tumors of the pericardium or mediastinum are fibromas, angiomas, and teratomas. Pericardial mesothelioma can have a clinical course characterized by rapid accumulation of massive quantities of bloody pericardial fluid, eventually leading to tamponade. Secondary involvement of the pericardium may result from either direct invasion from structures or metastases from a distant primary tumor. These metastases are usually multiple rather
than solitary lesions. The tumors most commonly associated with pericardial involvement include those of the lung and breast, leukemia, Hodgkin’s and non-Hodgkin’s lymphomas, melanomas, GI primary tumors, and sarcomas. Clinically recognizable symptoms or signs of pericardial disease are difficult to appreciate before death. Less than 30% of patients with autopsy-proven malignant pericardial disease were diagnosed antemortem.

Radiation pericarditis has been a well-known complication of radiotherapy since the introduction of modern megavoltage techniques. The cardiac effects of radiotherapy may manifest themselves immediately with acute pericarditis or be delayed for months to years, although the majority develop effusion within the first year. The acute forms are inflammatory or effusive, usually self-limited, and subside without residual constriction; the chronic effusive and constrictive types may lead to tamponade and death.

Neoplastic constrictive pericarditis, although rare, may be caused by the invasion of the pericardium by metastatic lesions or indirectly from the complication of radiotherapy with resultant fibrous thickening of the pericardium. Each of these entities can progress to cardiac tamponade because of thickening by tumor or radiation fibrosis, resulting in a decrease in the distensibility of the pericardium, thus reaching the critical point of cardiopulmonary decompensation earlier, despite smaller volumes of slowly accumulating effusion.

The symptoms and signs of neoplastic and radiation pericarditis mimic pericarditis from other causes, and because of the usual insidious onset of the effusion of fibrous pericardial thickening, the condition might be attributed to the underlying malignancy and not considered until the full-blown picture of cardiac tamponade develops.

Pathophysiology
The severity of cardiac tamponade and eventual cardiopulmonary decompensation depend on the rate of pericardial fluid accumulation, the fluid volume, and the underlying cardiac function. Clinically the progressive elevation of intracardiac pressure interferes with ventricular expansion and results in a decrease in the cardiac volume. Intracardiac chamber pressures rise rapidly with subsequent transmission of this pressure peripherally in pulmonary and vena caval beds. In an effort to maintain cardiac output, various compensatory mechanisms come into play (tachycardia, peripheral vasoconstriction, decrease in renal flow with resultant increase in blood volume by sodium and water retention), all to maintain arterial pressure and venous return. When these compensatory mechanisms fail to maintain cardiac output, ventricular end-diastolic pressure increases and subsequent circulatory collapse is impending. The signs and symptoms parallel these pathophysiologic changes. The most common symptoms include extreme anxiety and apprehension, a precordial oppressive feeling, or actual retrosternal chest pain with dyspnea of varying degrees. True orthopnea and paroxysmal nocturnal dyspnea are uncommon, but when they occur the patient assumes a variety of positions to get relief from the chest pain and the dyspnea. Other prominent symptoms include cough, hoarseness, hiccups, and occasional GI manifestations such as dysphagia, nausea, vomiting, and epigastric or right upper quadrant abdominal pain that is probably the result of visceral congestion.

Clinical Features
Patients with severe tamponade are acutely ill and may appear ashen, pale, or markedly diaphoretic with an impaired consciousness ranging from mildly confused to unresponsive. Rapid, shallow, and occasionally labored breathing may be present along with peripheral cyanosis and distended jugular veins. Seizures have been reported. Striking facial plethora and a full neck secondary to edema (Stoke’s collar) can also be seen in SVCs. Pulses are soft and easily compressible. The systolic blood pressure is usually low, with a decreased pulse pressure, although normal systolic, diastolic, and pulse pressures have been reported with moderate degrees of tamponade. Kussmaul’s signs (muffled heart sounds, an enlarged cardiomegaly, and aortic regurgitation) are extremely useful findings in the physical evaluation of tamponade (Table 121-1). Ascites, hepatomegaly, peripheral edema, and mottling are other findings that reflect the elevation in venous pressure and decrease in cardiac output.

Ancillary Evaluation
Low-voltage and the nonspecific findings of pericardial effusion, sinus tachycardia, ST elevation, and nonspecific ST-T wave changes may occur. Electrical alternans with 1:1 total atrial-ventricular complexes has been considered almost pathognomonic of cardiac tamponade. Electrical alternans is the alternation of electrocardiographic QRS complexes, usually

<tbody>
<tr>
<td><strong>Beck Triad or Acute Compression Triad</strong></td>
<td>Described in 1935, this complex of physical findings refers to increased jugular venous pressure, hypotension, and diminished heart sounds. These findings result from a rapid accumulation of pericardial fluid. However, this classic triad is usually observed in patients with acute cardiac tamponade.</td>
</tr>
<tr>
<td><strong>Pulsus Paradoxus or Paradoxical Pulse</strong></td>
<td>This is an exaggeration (&gt;12 mm Hg, or 9%) of the normal inspiratory decrease in systemic blood pressure. To measure the pulsus paradoxus, patients are often placed in a semirecumbent position; respirations should be normal. The blood pressure cuff is inflated to at least 20 mm Hg above the systolic pressure and slowly deflated until the first Korotkoff sounds are heard only during expiration. At this pressure reading, if the cuff is not further deflated and a pulsus paradoxus is present, the first Korotkoff sound is not audible during inspiration. As the cuff is further deflated, the point at which the first Korotkoff sound is audible during both inspiration and expiration is recorded. If the difference between the first and second measurement is greater than 12 mm Hg, an abnormal pulsus paradoxus is present. The paradox is that while listening to the heart sounds during inspiration, the pulse weakens or may not be palpated with certain heartbeats, while S1 is heard with all heartbeats. A pulsus paradoxus can be observed in patients with other conditions, such as constrictive pericarditis, severe obstructive pulmonary disease, restrictive cardiomyopathy, pulmonary embolism, rapid and labored breathing, and right ventricular infarction with shock. A pulsus paradoxus may be absent in patients with markedly elevated left ventricular diastolic pressures, atrial septal defect, pulmonary hypertension, and aortic regurgitation.</td>
</tr>
<tr>
<td><strong>Kussmaul’s Sign</strong></td>
<td>This was described by Adolph Kussmaul as a paradoxical increase in venous distention and pressure during inspiration. This sign is usually observed in patients with constrictive pericarditis but occasionally is observed in patients with effusive-constrictive pericarditis and cardiac tamponade.</td>
</tr>
</tbody>
</table>
in a 2:1 ratio. This is due to movement of the heart in the pericardial space. Electrical alternans is also observed in patients with myocardial ischemia, acute pulmonary embolism, and tachyarrhythmias.41

Approximately two thirds of the reported cases of pulsus alternans occur in patients with tamponade caused by massive pericardial effusion in neoplastic pericarditis. The alternation customarily disappears soon after removal of a small volume of fluid, but it can also disappear spontaneously or be observed in attendance with a fluid increase.41

Radiographic signs of tamponade suggestive of pericardial effusion include an enlarged cardiac silhouette with clear lung fields and normal vascular pattern, although a normal chest radiograph does not exclude tamponade. The typical “water-bottle” appearance of the heart on a plain radiograph is often present.

Echocardiography is the simplest and most sensitive of diagnostic tests and can be done at the bedside for confirmation of pericardial effusion. Thoracic CT has also become an important diagnostic tool in diagnosing pericardial effusions.41,46

Cardiac tamponade should be considered in any cancer patient with dyspnea. Highly suggestive symptoms include clouded sensorium, thready pulse, pulsus paradoxus exceeding 50% of the pulse pressure, low systolic pressure, engorged neck veins with a rising peripheral venous pressure above 130 mm H₂O, a falling pulse pressure below 20 mm Hg, and electrical alternans. This is an uncommon yet pathognomonic sinusoidal variation in QRS size secondary to the pendular effect of the heart swinging in the fluid medium of the pericardial sac.45 In this setting, sudden death may occur and pericardiocentesis should be performed as soon as possible.

Management

In the ED, the only lifesaving treatment for tamponade that is effective is immediate removal of the pericardial effusion via pericardiocentesis. The procedure carries some risk, including induction of cardiac dysrhythmias and hemorrhage from an injured coronary vessel. Aspiration of as little as 50 to 100 mL of fluid has been shown to temporarily alleviate the pathologic process.12,40,41

Emergency subxiphoid percutaneous drainage is a lifesaving bedside procedure. The subxiphoid approach is extrapleural; hence, it is the safest for blind pericardiocentesis. A 16- or 18-gauge needle is inserted at an angle of 30 to 45 degrees to the skin, near the left xiphocostal angle, aiming toward the left shoulder. When performed emergently, this procedure is associated with a reported mortality rate of approximately 4% and a complication rate of 17%.41

Echocardiographically guided pericardiocentesis can also be performed in the ED, but the cardiac catheterization laboratory is a more controlled setting and is preferable: this is usually performed from the left intercostal space. First, mark the site of entry based on the area of maximal fluid accumulation closest to the transducer. Then, measure the distance from the skin to the pericardial space. The angle of the transducer should be the trajectory of the needle during the procedure. Avoid the inferior rib margin while advancing the needle to prevent neurovascular injury. Leave a 16-gauge catheter in place for continuous drainage.41

Removal of the maximal amount of fluid is advisable, along with inserting of an indwelling catheter, during the first pericardiocentesis since fluid may reaccumulate during the first 24 hours. Once the pericardial fluid has been obtained, it must be sent for biochemical and cytologic analysis. Neoplastic cardiac tamponade accounts for at least 50% of all reported cases of pericardial fluid collection. Other types of supportive therapy may be needed during the evaluation process while preparing for pericardiocentesis, such as IV hydration with normal saline and oxygen therapy.

Once the patient has been stabilized, additional therapeutic interventions should be planned and initiated by the appropriate admitting services because reaccumulation of effusion in neoplastic tamponade is not easily managed on a short-term basis. Pericardial windows, radiotherapy, intrapericardial chemotherapy, and pericardectomy may be justified.12,40,41

The prognosis after neoplastic cardiac tamponade depends on the underlying type and extent of cancer. The presence of total electrical alternans is an adverse prognostic sign, even when the alternans disappears with pericardiocentesis. Despite a poor prognosis for patients with cancers such as melanoma or non-small-cell lung cancer, some patients with treatment-responsive lymphomas have survived long-term after neoplastic cardiac tamponade.

NEUROLOGIC EMERGENCIES

Of all patients with cancer, 15 to 20% have neurologic complications.45 Neurologic symptoms are occasionally the presenting complaint in patients with systemic cancer, but more often symptoms develop in patients known to have cancer. Neurologic emergencies in cancer patients include cerebral herniation, seizures, epidural spinal cord compression, CNS infections, and reversible toxic or metabolic encephalopathies. Treatment is needed urgently after the patient arrives at the ED to prevent permanent neurologic dysfunction or death.

CEREBRAL HERNIATION

Pathophysiology

Cerebral herniation occurs when the ICP increases locally within the skull from an expanding mass lesion. The increase produces a shift of brain substance in the direction of least resistance caudally through the tentorial opening and the foramen magnum. Causes of cerebral herniation in cancer patients commonly include primary or metastatic brain tumors and intracerebral hemorrhage. Less common causes include subdural hematoma, brain abscess, acute hydrocephalus, and radiation-induced brain necrosis.46 Primary brain tumors account for approximately one half of intracranial tumors. Metastatic brain tumors are seen most commonly in lung, breast, colon, kidney, and testicular cancer and in patients with choriocarcinoma and malignant melanoma.47,48

Clinical Features

Three distinct herniation syndromes have been described: uncal, central, and tonsillar herniation. In uncal herniation a lateral mass displaces the temporal lobe, which compresses the upper brainstem. A rapid loss of consciousness is seen in conjunction with unilateral pupillary dilatation and ipsilateral hemiparesis. Central herniation usually results from slowly expanding, multifocal lesions that cause a downward and lateral shift of the diencephalon and upper pons. A slowly decreasing level of consciousness, small reactive pupils, and Cheyne-Stokes respirations, without focal signs, are seen clinically. Central herniation is sometimes mistaken for toxic or metabolic encephalopathy because of the lack of focal signs. A history of headache or focal neurologic complaints or any lateralizing findings indicates the need for prompt CT of the head to rule out a herniating mass lesion before lumbar puncture. Tonsillar herniation is produced by a large posterior fossa mass that pushes the cerebellar tonsils through the foramen magnum, compressing the medulla and resulting in a rapidly decreasing level of consciousness, occipital headache, vomit-
ing, hiccups, hypertension, meningismus, and abrupt changes in the respiratory pattern.\(^{47-50}\)

**Management**

When the clinical diagnosis of cerebral herniation is made, emergency management is necessary before the cause can be established. Intubation with hyperventilation to a carbon dioxide partial pressure (Pco\(_2\)) of 25 to 30 mm Hg temporarily lowers the ICP by producing cerebral vasoconstriction. This should be avoided if possible but may be necessary for brief periods in response to reversible, acute neurologic deterioration. Excessive or prolonged hyperventilation may cause paradoxical vasodilation and should be avoided. Mannitol (1 g/kg IV) should be given and may be repeated in 4 to 6 hours. Dexamethasone (12–24 mg IV) has not been shown to improve outcome or reduce ICP acutely in severe head injury,\(^{51,52}\) but is often administered in patients with raised ICP or impending herniation caused by CNS malignancy because of the effect of corticosteroids on reducing cerebral edema associated with the neoplastic process. CT of the brain should be obtained as soon as emergency stabilization is accomplished. Epidural or subdural hematoma and hydrocephalus usually require surgery, whereas abscess and metastases are usually managed with antibiotics and antineoplastics or radiation, or both, respectively. When stabilization and an initial diagnosis have been made, neurologic or neurosurgical consultation and prompt admission to an intensive care unit are mandatory.\(^{37,49}\)

**SEIZURES**

Seizures are common in patients with cancer. Their immediate management is necessary to prevent physical injury, increased ICP, and risk of aspiration. Seizures increase the brain’s metabolic requirements and lead to increased cerebral blood flow. This may precipitate increased ICP in susceptible patients. Seizures may be due to brain metastases, toxic or metabolic disturbances (usually hyponatremia or uremia), vascular problems (especially intracerebral hemorrhage or subdural hematomas), and infections. Diagnostic laboratory studies should include a CBC, electrolytes, glucose level, blood urea nitrogen (BUN), measurement of calcium and magnesium levels, liver function tests, coagulation studies, and appropriate cultures. CT of the head should be done and followed by a lumbar puncture, when indicated.\(^{37,49}\)

The therapy for seizures depends on the specific cause and the patient’s clinical status. For example, a single hypoglycemic or hypoxic seizure usually requires only correction of the underlying metabolic defect. Patients with a single seizure whose workup reveals a chronic problem (e.g., a cerebral metastasis) require anticonvulsants and therapy specific for the malignancy. A loading dose of phenytoin (15–18 mg/kg IV) may be given followed by oral maintenance. Prolonged single seizures or repetitive seizures require more vigorous treatment, including diazepam (5–10 mg IV) or lorazepam (1–2 mg IV) followed by IV phenytoin. Active airway and ventilatory management is essential. A bedside fingerstick glucose level should be obtained promptly. Thiamine and naloxone are not routinely indicated. In addition, when repetitive seizures have occurred, management of the underlying cause should be initiated rapidly and the patient admitted to an intensive care unit.\(^{37,49}\)

**EPIDURAL SPINAL CORD COMPRESSION**

**Principles of Disease**

Epidural spinal cord compression from metastatic cancer is common, serious, and potentially treatable. It is most often caused by lymphoma or lung, breast, or prostate carcinoma. With the exception of lymphoma, which extends through the intervertebral foramina from paravertebral lymph nodes, these tumors metastasize to the vertebral body and extend into the spinal canal to compress the spinal cord. Less common causes of spinal cord compression in patients with cancer include melanoma, myeloma, renal cell carcinoma, vertebral subluxation, spinal epidural hematomas, and intramedullary metastasis. Acute myelopathy in patients with cancer may also be caused by radiation, paraneoplastic necrotizing myelitis, a ruptured intervertebral disk, and meningeal carcinomatosis with spinal cord involvement. Most cases (68%) of epidural cord compression occur in the thoracic spine, 15% occur in the cervical spine, and 19% in the lumbosacral spine.\(^{53}\)

**Clinical Features**

Back pain, either local or radicular, is the initial symptom in 95% of patients with epidural metastasis. It may be acute in onset or develop insidiously over weeks to months and usually predates other symptoms. The pain may increase during physical examination with spinal percussion, neck flexion, Valsalva maneuver, or straight leg raising and is usually located at the level of the tumor.\(^{50,54,55}\) Other symptoms are usually present at the time of diagnosis and may include weakness (75% of patients) and autonomic or sensory symptoms (50% of patients). Fifty percent of patients are not ambulatory at the time of diagnosis. The neurologic examination usually reveals symmetrical weakness with either flaccidity and hyporeflexia (if the diagnosis is made very early) or spasticity and hyperreflexia (if the diagnosis is made later).

**Diagnostic Strategies**

Plain films show evidence of tumor in the vertebral body in 70 to 90% of patients with vertebral metastases.\(^{47,51}\) Immediate myelography or MRI is indicated if the plain films are abnormal, regardless of whether the neurologic examination is abnormal or is consistent with spinal cord compression or the plain film findings. In cases with questionable findings on plain films of the spine, tomograms, coned-down views, or CT may reveal bone metastases not otherwise appreciated. Myelography can demonstrate a complete or near-complete obstruction of contrast dye flow at the level of vertebral body involvement. MRI has emerged as the procedure of choice for intramedullary metastases and has also replaced myelography, which is associated with significant morbidity related to lumbar puncture and dye insertion at multiple levels (including cisternal puncture), to demonstrate the length of the compression or skip lesions along the spinal cord.\(^{50,55}\)

**Management**

Because minimal weakness at the time of presentation may progress to profound, irreversible weakness over several hours, treatment should be started rapidly. In the ED, a loading dose of dexamethasone (10–100 mg IV), followed by 4 to 24 mg every 6 hours for 3 days to reduce cord edema, is initiated at the time of diagnosis. Immediate oncology and radiation oncology consultations should be obtained. Although corticosteroids are routinely administered to patients with suggested spinal cord compression, high-dose corticosteroids, such as dexamethasone (100 mg), have been associated with complications and their use is controversial.\(^{53}\) Radiation treatment is the usual therapy and can be initiated after steroid treatment. The prognosis depends on the radiosensitivity of the tumor, the location of the compression, the pretreatment performance status, and the rate of decompensation. Surgery is indicated
only if the diagnosis is in doubt, if a tissue diagnosis is required, if the spine is unstable, or when maximal doses of radiation have already been given to the involved area.47,48,56

Intramedullary metastases are similar in presentation and treatment to epidural compression but are associated with a very poor prognosis. Epidural hematomas have been described in patients with thrombocytopenia or a coagulopathy as a complication of lumbar puncture. A rapidly progressive paraparesis and back pain are seen. MRI or myelography can establish the diagnosis; the treatment is surgical decompression. Platelet transfusions may limit progression in the ED.47,56

**CENTRAL NERVOUS SYSTEM INFECTIONS**

**Principles of Disease**

Patients with cancer are susceptible to a variety of CNS infections. These patients may have impaired immune responses secondary to their underlying disease or treatment with steroids, chemotherapy, splenectomy, or irradiation. Most CNS infections occur in patients with leukemia, lymphoma, or head and neck cancer. Patients with head and neck cancer are susceptible (in addition to the reasons discussed) because of fistula formation and tumor invasion, which allows organisms access to the CNS. Important CNS infections include meningitis, brain abscess, and encephalitis. These often have similar presentations, making their differentiation in the ED difficult.

**Clinical Features**

Meningitis is characterized by fever, headache, and altered mental status. Meningismus is often absent. The diagnosis of meningitis in patients with cancer is often delayed because the manifestations of the disease are attributed to other processes: fever to systemic infection, headache to cerebral metastases, and altered mental status to a toxic or metabolic encephalopathy.

**Diagnostic Strategies**

All cancer patients with fever and an altered mental status require a lumbar puncture, which should be preceded by head CT if cerebral metastases are suggested.49,52 In addition, thrombocytopenia and coagulopathy should be considered and either ruled out or treated appropriately with platelet transfusions or fresh frozen plasma, respectively, before a lumbar puncture is done. Platelet transfusion is usually reserved for patients with platelet count less than 10,000/μL. The fluid obtained should be sent for a cell count and differential cell count, Gram’s stain, India ink stain, protein and glucose levels, bacterial and fungal cultures, cryptococcal antigen level, and cytologic examination. The absence of WBCs in the cerebrospinal fluid does not rule out meningitis, especially in neutropenic patients. The likely organisms responsible for meningitis vary with the underlying disease and the peripheral WBC count.

**Differential Considerations**

Brain abscess is usually seen in patients with leukemia or head and neck tumors and accounts for 30% of CNS infections in cancer patients.49 Patients have symptoms of elevated ICP (headache, vomiting, and papilledema), lateralizing findings, and a source of infection.49,52 Fever is usually present. Head CT characteristically demonstrates an ill-defined mass early in the course of an abscess, with the classic well-defined mass with a low-density center and a contrast-enhancing ring seen later. Edema and mass effect are common. A lumbar puncture is not helpful in making the diagnosis and may precipitate cerebral herniation. Organisms that cause abscess include gram-negative rods, *Aspergillus* and *Phycomycetes* species, and *Toxoplasma gondii*. Emergency management includes high-dosage antibiotics. If herniation develops, immediate steps to reduce the ICP, followed by emergency surgery, are indicated.

Encephalitis is rare in patients with cancer and is most often caused by herpes zoster or *T. gondii*. The presenting complaints are usually headache, fever, and altered mental status. The CT scan is commonly normal but may show diffuse edema, whereas the lumbar puncture may show pleocytosis with an elevated protein level but no demonstrable organism. It is difficult to distinguish encephalitis from meningitis in the ED, but the overall clinical picture in both diseases mandates hospital admission for further evaluation.

**Management**

Until further evaluation is able to distinguish between meningitis and encephalitis, empirical broad-spectrum antibiotic coverage with a third-generation cephalosporin (ceftriaxone or ceftazidime) and vancomycin should be initiated for all patients. Ampicillin may be added when there is suggestion of *Listeria*. Ceftazidime with or without an aminoglycoside is generally selected when the likelihood of infection with *Pseudomonas* is high. Neutropenic patients (polymorphonuclear WBC count < 1000/mm³) with either leukemia or lymphoma usually have a gram-negative infection (often with *P. aeruginosa*). Patients with lymphoma and a normal WBC count are commonly infected with *Listeria monocytogenes*, *Streptococcus pneumoniae*, or *Cryptococcus neoformans*. Infections with *Haemophilus influenzae* and *Neisseria meningitidis* are uncommon. Patients with head and neck tumors may develop staphylococcal infection.47-50
KEY CONCEPTS

- Hypercalcemia due to malignancy is unrelated to bone metastases in 20% of patients and is associated with a poor prognosis independent of therapeutic response. Hydration and use of bisphosphonates (e.g., pamidronate) have become the mainstays of initial treatment.
- Spinal cord compression arises as back pain in more than 95% of patients. If ambulatory at the time of diagnosis, 80% of patients maintain the ability to ambulate. MRI has become the diagnostic modality of choice, and high-dose dexamethasone is given to all patients, followed by radiation therapy in most cases.
- Superior vena cava obstruction is rarely life-threatening and requires tissue diagnosis. Although caused by malignancy in 70 to 80% of cases, thrombosis secondary to indwelling central lines is increasing as a cause. Stenting of the SVC has become the approach to SVC obstruction unresponsive to chemotherapy or radiation therapy, or both.
- Fever and neutropenia in the cancer patient are a true medical emergency requiring rapid diagnosis, cultures, and treatment with broad-spectrum, bactericidal, synergistic antimicrobials. An aminoglycoside plus an extended-spectrum penicillin and third-generation cephalosporin with or without vancomycin remain the standard combinations in patients without penicillin allergy.
- Neoplastic pericardial effusion can arise insidiously with symptoms such as apprehension, anxiety, dyspnea, and weakness. Bedside ultrasonography has become a rapid, safe imaging modality for establishing the diagnosis prior to the development of clinically apparent tamponade in a critically ill patient.
- Acute TLS, previously limited to hematologic malignancies, is now being described in patients receiving chemotherapy for solid tumors. It can arise with dyspnea, mental status changes, cardiac dysrhythmia, or seizures. Treatment includes urinary alkalinization and emergency hemodialysis in cases complicated by acute renal failure.

The references for this chapter can be found online by accessing the accompanying Expert Consult website.
The human body must be maintained in a precise acid-base balance to maintain healthy cellular function. This balance is controlled by the lungs, kidneys, and serum buffers, interacting and responding to physiologic changes. Physiologic insults such as vomiting, diarrhea, respiratory failure, kidney dysfunction, diabetes, toxic ingestions, among others can result in life-threatening acid-base crises. Identifying and optimally treating the underlying condition is often achieved only through the diagnostic insights gained from acid-base measurements and calculations. This chapter presents essential acid-base physiology, beginning with an overview of the principles of acid-base function. This is followed by a discussion of primary respiratory acidosis and alkalosis and then metabolic causes of acidosis and alkalosis. Finally, mixed acid-base disorders are analyzed. Clinical implications are included along with the mathematical knowledge that the emergency physician requires to expertly manage these complex and potentially life-threatening conditions.

**PRINCIPLES OF DISEASE**

The kidneys, lungs, and physiologic buffers normally maintain the serum pH within a narrow spectrum, between 7.36 and 7.44. Each of these three systems dynamically responds to small changes in acid-base balance. Such precise physiologic control is required for normal cellular function. Consequently, disorders of kidneys, lungs, and physiologic buffers result in acid-base abnormalities.

Blood pH is determined by the ratio of the serum bicarbonate concentration and Pa\(\text{CO}_2\) (partial pressure of CO\(_2\) in arterial blood). Primary metabolic acid-base disorders and the secondary metabolic compensation for primary respiratory disturbances alter the serum bicarbonate concentration \([\text{HCO}_3^-]\). Primary respiratory acid-base disorders and the secondary respiratory compensation for primary metabolic disturbances alter the Pa\(\text{CO}_2\).

The Henderson-Hasselbalch equation relates the concentrations of the acid-base pair to the pH. As the pH changes, so does the concentration. Because the equation produces a logarithmic result, subtle changes in the serum pH can cause large and often significant alterations in the concentration of the acid-base pair. Clinically, this equation dictates how drugs disperse, enzymes react, and medications bind at a given serum pH. In humans, hydrogen ion concentration \([\text{H}^+]\) is extremely low (approximately \(4 \times 10^{-12}\) mEq/L) and strictly regulated. Normally, blood is slightly alkalemic relative to water (pH 7.0). Blood pH must be maintained within relatively narrow limits because protein and enzyme systems function properly only within a narrow pH spectrum. A pH outside the range of 6.8 to 7.8 is generally associated with serious disease processes and the potential for considerable morbidity or mortality.

Acidemia is defined as a serum pH of less than 7.36. Conversely, alkalemia is defined as a pH of greater than 7.44. Acidosis is defined as a pathologic process that lowers the \([\text{HCO}_3^-]\) (metabolic acidosis) or raises the Pa\(\text{CO}_2\) (respiratory acidosis); alkalosis is defined as a pathologic process that raises the \([\text{HCO}_3^-]\) (metabolic alkalosis) or lowers the Pa\(\text{CO}_2\) (respiratory alkalosis). A simple acid-base disorder is a single acid-base disturbance with its accompanying compensatory response. Mixed acid-base disorders are the result of two or more primary disturbances.

**Physiologic Buffers**

Physiologic buffers, defined as a weak acid and its salt, oppose marked changes in pH after the addition of an organic acid or a base, as follows:

\[
\text{H}^+ + \text{buffer}^+ \text{Na}^+ \rightleftharpoons \text{buffer}^- \text{H}^+ + \text{Na}^+
\]

The human body uses three important physiologic buffers to minimize surges in pH: (1) the bicarbonate/carbonic acid system (primarily located in red blood cells), (2) intracellular protein buffers, and (3) phosphate buffers located within bone. Patients with malnutrition or chronic disease, and thus low albumin and bone density, and anemic patients have an ineffective buffering capability.

**Bicarbonate/Carbonic Acid Buffer System**

The bicarbonate/carbonic acid buffer system is unique among physiologic buffering systems. The system is open-ended; continuous removal of organic acid is made possible by the exhalation of carbon dioxide (CO\(_2\)). In equilibrium, the equation is as follows:

\[
\text{H}^+ + \text{HCO}_3^- \rightleftharpoons \text{H}_2\text{CO}_3 \rightleftharpoons \text{H}_2\text{O} + \text{CO}_2
\]

Bicarbonate is present in large quantities and can be controlled by the lungs and kidneys; thus, it serves as the major contributor to the maintenance of acid-base balance. Clinically, its importance is in the transient buffering of serum and interstitial fluid.
Intracellular Protein Buffers

Many protein buffers in blood are effective in maintaining acid-base homeostasis. Plasma proteins, particularly albumin and hemoglobin, can buffer large amounts of H⁺, preventing significant changes in the pH. If hemoglobin did not exist, venous blood would be 800 times more acidic than arterial blood, circulating at a pH of 4.5 instead of the normal venous pH of 7.37.

Bone as Buffer

Bone contains a large reservoir of bicarbonate and phosphate and can buffer a significant acute acid load. Bone is probably involved in providing some buffering (mostly ionic exchange) in most acute acid-base disorders, but there is very little research in this area. In terms of duration, only two types of metabolic acidosis are long-lasting enough to be associated with the loss of bone mineral (through release of calcium carbonate): renal tubular acidosis and uremic acidosis. In uremic acidosis, loss of bone crystal is multifactorial (changes in vitamin D metabolism, phosphate metabolism and secondary hyperparathyroidism) and acidosis is only a minor factor.

Pulmonary Compensation

The second compensatory system for pH changes involves a relationship between the peripheral chemoreceptors, located in the carotid bodies, and central chemoreceptors, located in the medulla oblongata. Both these receptors influence respiratory drive and can initiate changes in minute ventilation. A drop in pH stimulates the respiratory center, resulting in increased minute ventilation. This in turn lowers the PaCO₂, driving the pH toward the normal range. Conversely, an increase in pH decreases ventilatory effort, which increases PaCO₂ and lowers the pH back toward normal. A diabetic patient in ketoacidosis hyperventilates to compensate for the organic acidemia and would be expected to have a low PaCO₂. This compensatory response is the expected reaction to a fall in serum pH. In general, compensatory processes return the pH toward normal over a period of 4 to 12 hours, but do not fully normalize it. Respiratory alkalosis is the only primary acid-base disorder in which the pH does often normalize with time.

Renal Compensation

The kidneys play little role in the acute compensation of acid-base disorders because they do not immediately respond to changes in pH. More than 6 to 12 hours of sustained acidosis results in active excretion of H⁺ (predominantly in the form of ammonium, NH₄⁺, with retention of bicarbonate, HCO₃⁻). Conversely, more than 6 hours of alkalosis stimulates renal excretion of bicarbonate with retention of H⁺ in the form of organic acids, resulting in near-normalization of pH.

In metabolic acidosis, there is either an excess production or an infusion of H⁺ (e.g., lactic acid production, ketoacid production) or an excessive loss of anion (HCO₃⁻) and accompanying sodium and potassium cations (Na⁺, K⁺; e.g., diarrhea). In general, the kidneys attempt to preserve Na⁺ by exchanging it for excreted H⁺ or K⁺. The quantity of potassium excreted depends on the level of acidosis and the serum K⁺ level. In the presence of an H⁺ load, hydrogen ions move from the extracellular fluid (ECF) into the intracellular fluid. For this to occur, K⁺ moves outside the cell into the ECF to maintain electroneutrality. In cases of severe acidosis, significant overall depletion of total body K⁺ stores can occur despite serum hyperkalemia. Clinically, this is the rationale for initiating intravenous administration of K⁺ in the patient with diabetic ketoacidosis (DKA) and good renal function, despite an often elevated serum K⁺ level.

In metabolic alkalosis, there is a shift of H⁺ extracellularly, accompanied by an electoneutral shift of serum Na⁺ and K⁺ intracellularly. Renal excretion of K⁺ also occurs in an attempt to preserve H⁺. If the alkalosis continues, the renal compensation may be unable to keep pace, especially if hypokalemia ensues. With excessive total body depletion of K⁺ (usually as the result of nasogastric suction or some other inciting event), the kidney paradoxically begins to excrete H⁺ in an attempt to retain K⁺; thus, an aciduria can coexist with a serum alkalosis. This paradoxical aciduria is a clinical clue to the magnitude of hypokalemia and explains why renal compensation is unable to correct for alkalosis until K⁺ levels are restored.

Conditions that change serum K⁺ also alter serum pH. Excessive diuresis, occurring without potassium supplementation, generate a mild alkalalemia, as H⁺ is shifted intracellularly to support the extracellular osmotic movement of K⁺. Conversely, excessive administration of potassium can cause H⁺ to shift extracellularly, which may produce a mild acidosis.

### DIAGNOSTIC STRATEGIES

A stepwise clinical approach to acid-base disorders starts with a well-conducted history and physical examination. Particular attention should be paid to the patient’s past medical history, current medications, chance of toxic ingestion, occurrence of vomiting or diarrhea, level of consciousness on admission, respiratory rate, skin turgor, and urine output.

Evaluation progresses with analysis of serum electrolytes and pH, and calculation of any anion gap, and calculation of the delta gap. These calculations assist in determining the type of acidosis or alkalosis present and whether it is part of a mixed condition. The anion gap (AG) can be calculated as follows:

\[
AG = Na^+ - (Cl^- + HCO_3^-)
\]

Traditionally, a normal AG has been considered 12 ± 3 mEq/L. This number can vary from one laboratory to another (mostly based on whether potassium is included in the calculation) and the clinician should take this possibility into consideration. The “gap” provides an estimate of unmeasured anions in plasma, primarily albumin plus small amounts of sulfate, phosphate, and organic anions (e.g., citrate). If there are excess organic acids in the circulation, the organic acids dissociate and the resulting H⁺ is titrated by HCO₃⁻, which increases the AG. If the AG is increased, especially when it is more than 10 mEq/L above the upper limit of the reference range, the clinician should consider an excess in organic acids or acidic substances. With smaller gaps up to one third of patients will not have a metabolic acidosis. The concept of a “low” AG (<3 mEq/L) may be useful in the diagnosis of lithium toxicity, immunoglobulin G myelomas, and hypoalbuminemia of chronic disease.

Calculating the delta gap (ΔG = deviation of AG from normal – deviation of HCO₃⁻ from normal) may help resolve the possibility of a mixed acid-base disorder or further differentiate an elevated AG metabolic acidosis. Mathematically refined and with normal values substituted, the equation is as follows:

\[
ΔG = (\text{calculated AG} - 12) - (24 - \text{measured HCO}_3^-)
\]

Values greater than +6 equate with metabolic alkalosis or respiratory acidosis. Values less than –6 imply a greater loss of HCO₃⁻, suggesting a mixed disorder.
RESPIRATORY ACIDOSIS

Respiratory acidosis is defined as decreased pH that results from pulmonary CO₂ retention. In other words, hypoventilation leads to hypercapnia. CO₂ retention results in excess H₂CO₃ production, which leads to acidemia. In the acute state, the serum [HCO₃⁻] is normal. The transition from acute to chronic respiratory acidosis is defined as the point at which renal compensation manifests as HCO₃⁻ retention (Fig. 122-1).

Clinical Features

Respiratory acidosis is caused by any disorder that results in a decrease in minute ventilation and thus CO₂ retention. Common causes include pulmonary pathologic conditions, airway obstruction, and conditions that influence respiratory drive (Box 122-1). The clinical picture depends on the severity and chronicity of the process as well as on the underlying disease. Patients with acute respiratory acidosis may have CO₂ narcosis, characterized by symptoms and signs such as headache, asterixis, weakness, tremors, blurred vision, confusion, or somnolence. If prolonged, signs of intracranial pressure elevation with papilledema become manifest.

Physiologic Compensation

In acute respiratory acidosis, the only effective buffers are the intracellular proteins. The HCO₃⁻ formed by intracellular buffering diffuses out of the cell into the ECF, increasing about 1 mEq/L for every 10-mm Hg rise in the PaCO₂. In acute situations, this HCO₃⁻ compensation is insignificant and has only minimal effect on the prevailing pH. Profound acidemia develops quickly if ventilation is not improved.

In chronic respiratory acidosis, such as chronic obstructive pulmonary disease, renal retention of HCO₃⁻ plays a significant role in acid buffering. The initial response occurs beyond the first 6 to 12 hours and takes several days to reach maximal contribution. Chloride (Cl⁻) is excreted to maintain electrical neutrality and results in the characteristic hypochloremia of a chronic respiratory acidosis. Plasma [HCO₃⁻] increases approx-

Causes of Respiratory Alkalosis

The plasma $[\text{HCO}_3^-]$ is lowered approximately 2 mEq/L for every 10-mm Hg increase in the $\text{Paco}_2$. This response provides excellent compensation and nearly normalizes the pH.

Management

Therapy of acute respiratory acidosis is directed toward correction of minute ventilation, thus returning the $\text{Paco}_2$ to normal. This may entail establishment of a definitive airway, initiation of artificial respiration, or treatment of an underlying toxic or neurologic condition.

Likewise, improving ventilation treats chronic respiratory acidosis. Bronchodilators, postural drainage, and antibiotics for infection are used to manage the underlying cause. In patients with chronic respiratory acidosis, sensitivity of the respiratory center progressively decreases with prolonged exposure to acidosis and hypercapnia, resulting in a ventilatory drive that depends on relative hypoxemia. Administration of oxygen to these patients reduces their hypoxic drive and minute ventilation, potentially creating CO$_2$ narcosis. Therefore, oxygen must be given with caution to patients with chronic respiratory acidosis. If the patient has severe hypoxemia, however, sufficient oxygen must be administered and the physician should be prepared to actively manage airway and ventilation. If assisted ventilation is required, the $\text{Paco}_2$ should be lowered slowly to avoid posthypercapnic metabolic alkalosis.

In patients with known coronary artery disease, research suggests that acute respiratory acidosis leads to direct vasodilation of coronary vasculature. This is believed to be an instinctive attempt to maintain myocardial blood flow.

RESPIRATORY ALKALOSIS

Increased minute ventilation is the primary cause of respiratory alkalosis, characterized by decreased $\text{Paco}_2$ and increased pH. Patients with uncompensated acute respiratory alkalosis have normal plasma $[\text{HCO}_3^-]$. In chronic respiratory alkalosis, eventual renal compensation results in decreased plasma $[\text{HCO}_3^-]$.

Etiology

Conditions that lead to respiratory alkalosis are central nervous system (CNS) diseases, hypoxemia, anxiety, hysteria, hypermetabolic states, toxic states, hepatic insufficiency, and assisted ventilation (Box 122-2).

Clinical Features

Symptoms vary according to the degree and chronicity of the alkalosis and the associated symptoms caused by the underlying disorder. The symptoms of alkalosis result from irritability of the central and peripheral nervous systems and from increased resistance in the cerebral vasculature. Symptoms include paresthesias of the lips and extremities, lightheadedness, dizziness, muscle cramps, and carpopedal spasms; symptoms are identical to those seen with hypocalcemia.

Physiologic Compensation

Acute Alkalosis

After the onset of respiratory alkalosis, $H^+$ is secreted from within the cell to the ECF. $H^+$ reduces the plasma $[\text{HCO}_3^-]$, attempting to offset the acute alkalosis. During the acute state, the plasma $[\text{HCO}_3^-]$ is lowered approximately 2 mEq/L for each 10-mm Hg decrease in the $\text{Paco}_2$.

Chronic Alkalosis

With persistently low $\text{Paco}_2$, renal $H^+$ secretion is decreased. Mild hypokalemia often occurs as $K^+$ shifts into the cells while $H^+$ enters the ECF. Renal secretion of $\text{HCO}_3^-$ occurs, and $\text{Cl}^-$ is retained to maintain electroneutrality. This creates the hypokalemia and hyperchloremia characteristic of a chronic respiratory alkalosis. During the first 7 to 9 days, compensation is insufficient to normalize the pH, and alkalemia prevails. Beyond 2 weeks, patients with a chronic respiratory alkalosis have a normal or near-normal pH, making this the only primary acid-base disorder in which the pH does often normalize.

Alkalemia of pregnancy (pH 7.46–7.50) is primarily respiratory in origin, occurs early, and is sustained throughout the gestation. A $\text{Paco}_2$ of 31 to 35 mm Hg is considered normal in the antepartum period. Therefore, a $\text{Paco}_2$ of 40 mm Hg in the pregnant woman represents hypercapnia. In these patients, renal compensation leads to an excretion of $\text{HCO}_3^-$, and a serum $\text{HCO}_3^-$ level between 18 and 22 mEq/L in these women is normal.

Management

Respiratory alkalosis itself is rarely life-threatening, and treatment should be directed toward the underlying cause. Treatment should be aimed at removing the stimulus, and when that is not possible, at treating the symptoms. For example, benzodiazepines and pain control may benefit the patient who is overbreathing the ventilator, the anxious patient, or the cocaine or methamphetamine toxic patient. In the patient with tetany or syncope caused by psychogenic hyperventilating, a rebreathing mask allows for CO$_2$ retention and acid-base normalization. This should be used cautiously and only when other serious conditions have been eliminated from the differential diagnosis.
Metabolic acidosis is defined as acidemia created by a primary increase in \([H^+]\) or a reduction in \([HCO_3^-]\). The acute state is compensated for by hyperventilation, resulting in reduction of \(P_{CO_2}\). Chronically, renal reabsorption of \(HCO_3^-\) takes place (Fig. 122-2).

**Etiology**

Metabolic acidosis can be caused by one of three mechanisms: (1) increased production of acids, (2) decreased renal excretion of acids, or (3) loss of alkali. The causes of metabolic acidosis can be clinically divided into those that create an elevation in AG (Box 122-3) and those that do not (Box 122-4). Dehydration from prolonged diarrhea is the most common cause of normal gap metabolic acidosis.

**Elevated Anion Gap**

Metabolic acidosis with an elevated AG implies either the addition of exogenous acids or the creation of endogenous acids that cannot be fully neutralized by buffers. The causes can be broadly broken into ketoacidosis, lactic acidosis (either physiologic or from toxins), renal failure, toxins that are metabolized to acids, and, rarely, rhabdomyolysis.

**Carbon Monoxide and Cyanide Poisoning.** Elevated serum levels of carbon monoxide and cyanide have increasingly been found together in patients exposed to smoke from fires. Victims of smoke inhalation found unconscious and with metabolic acidosis should be considered to have been exposed to both agents. Known as cellular poisons, both toxins interfere with cellular respiration at the cytochrome/electron transfer stage, resulting in anaerobic metabolism and the generation of organic acidemia.

**Alcoholic Ketoacidosis.** Alcoholic ketoacidosis (AKA) results from an abrupt termination of ethyl alcohol intake after a significant and usually lengthy exposure to it. AKA also has a component of malnutrition and dehydration. Clinically, AKA manifests similarly to DKA; however, hyperglycemia and glycosuria are traditionally absent. Patients may present with AGs in the range of 30 to 35 mEq/L and hypocapnia secondary to compensatory hyperventilation. They may also have double and triple acid-base disorders due to alcohol withdrawal (respiratory alkalosis) and vomiting (metabolic alkalosis), which results in a pH that may be alkalemic. The ratio of \(\beta\)-hydroxybutyrate to acetoacetate is at least twice as high in AKA (6–10:1) as it is in DKA (3–4:1). This is important because there is a greater chance of missed diagnosis and inappropriate therapy in cases of AKA, since the \(\beta\)-hydroxybutyrate is not detected by the usual means and because during recovery, as \(\beta\)-hydroxybutyrate is converted to acetoacetate and acetone, a paradox-
Clinical worsening of the ketoacidosis results. (The usual dipstick tests have 0% sensitivity for β-hydroxybutyrate, 100% for acetacetate, and 5% for acetone.) The main treatment for AKA is hydration with 5% dextrose in normal saline (D5NS). Carbohydrate and fluid replacement reverse the pathophysiologic derangements that lead to AKA by increasing serum insulin levels and suppressing the release of glucagon and other counter-regulatory hormones. Fluids alone do not correct AKA as quickly as fluids and carbohydrates together, and in general, insulin is contraindicated.

**Toluene Inhalation.** Traditionally used as a solvent, toluene has become an inhalational agent abused for its euphoric effect. Toluene produces AG acidosis that is further complicated by distal renal tubular damage. The end result is a mix of non-AG and AG metabolic acidosis due to the renal tubular acidosis and HCO₃⁻ loss. Treatment is supportive and is aimed at fluid and electrolyte replacement when needed.

**Methanol, Ethylene Glycol, and Paraldehyde.** The toxic effects of methanol (methyl or wood alcohol) ingestion result from the formation of its metabolite, formaldehyde, which is converted to formic acid, which causes metabolic acidosis. Ethylene glycol’s toxic metabolites are oxalates, aldehydes, and lactic acid; oxalates result in significantly elevated AGs and increased mortality. Paraldehyde poisoning is rare; its use is now restricted to hospitalized patients and patients under close medical supervision. Ingestion leads to the creation of acetic and chloracetic acids. Treatment of methanol or ethylene glycol poisoning is aimed at preventing their metabolism into toxins with fomepizole or ethanol or elimination through hemodialysis.

**Uremia.** The acidosis in uremic patients results from a failure by the kidneys to excrete acids. H⁺ elimination is a direct secretory function of the renal tubules. The ability to excrete NH₄⁺, HSO₄⁻, and HPO₄²⁻ however, varies directly with the glomerular filtration rate (GFR). Any pathologic process affecting the GFR increases HSO₄⁻ and HPO₄²⁻, resulting in an increased AG. In cases of pure uremia, the AG rarely exceeds 25 mEq/L. In the patient with chronic renal failure, increased AG metabolic acidosis is common. In cases of acute renal failure, however, hyperchloremic, non-AG metabolic acidosis is more common.

In pyelonephritis or obstructive uropathy, the acidosis is not related to an increased AG because tubular function is affected more than GFR. Increased AG metabolic acidosis in the patient with elevated serum blood urea nitrogen and creatinine levels suggests renocortical disease.

**Diabetic Ketoacidosis.** DKA manifests clinically as a triad: hyperglycemia (usually >200 mg/dL), ketonemia (>1:2 dilutions), and acidemia (pH < 7.3). DKA can be caused by any condition that reduces insulin availability or activity or that increases glucagon. DKA occurs most often in type 1 diabetic patients with little or no endogenous insulin; however, its occurrence in patients with type 2 diabetes, particularly obese African Americans, is not as rare as once thought. DKA in these patients results from increased lipolysis, and the breakdown of free fatty acids leads to production of ketoads. Precipitating events usually include infections, surgery, and emotional or physical stressors. Treatment is aimed at fluid replacement over the first 24 to 48 hours, insulin replacement, and potassium replacement.

**Isoniazid and Iron Toxicity.** Isoniazid is a common, important, but potentially lethal medication used for the treatment of tuberculosis. Clinicians must be aware that ingestions of greater than 40 to 60 mg/kg pose a danger of not only recurrent seizures but also life-threatening metabolic acidosis (as a result of the lactate-producing seizures activity). Treatment involves pyridoxine administration to control seizures and hemodialysis to reduce both intravascular drug concentration and acidemia.

Elevated AG metabolic acidosis from iron ingestion is a direct result of mitochondrial poisoning and uncoupled oxidative phosphorylation. Metabolic acidosis is typically appreciated in phase I of toxicity, usually within 6 hours of ingestion. It becomes quite apparent in phase III, signaling impending hepatic failure and shock. Effective treatment depends on early recognition and administration of deferoxamine.

**Lactic Acidosis.** There are two forms of lactic acid, the levorotary, or “L,” form and the dextrorotary, or “D,” form. The L form is most common and is the traditional form measured when obtaining serum lactate levels. A product of anaerobic metabolism, lactic acidosis develops when an imbalance exists between lactic acid production and subsequent conversion by the liver and kidney. Thus, lactic acidosis is a marker of hyperperfusion and ongoing shock, as hyperperfusion, hypoxemia, hypermetabolic states, or some combination of these results in an increase in serum lactate.

The D form has recently gained attention because of an increasing number of patients with small-bowel resection or gastric bypass surgery. D-Lactic acidosis is characterized by episodes of encephalopathy and acidemia. Development of short-gut syndrome requires ingestion of a large carbohydrate load, carbohydrate malabsorption with increased delivery of carbohydrates to the large bowel, prominent lactobacilli, diminished colonic motility, and impaired D-lactic acid metabolism.

Nucleoside analogue reverse transcriptase inhibitors (e.g., zidovudine and stavudine) for human immunodeficiency virus have also been shown to induce lactic acidosis. The syndrome that results from the mitochondrial toxicity of these agents can manifest with severe lactic acidosis, hepatic steatosis, and a high rate of mortality. Initial measurement of metabolic acidosis (serum lactate levels), compared with the traditional carboxyhemoglobin levels, might better indicate the severity of carboxyhemoglobin toxicity and better predict hyperbaric treatment requirements.

Metformin, currently considered the initial drug of choice for overweight patients with type 2 diabetes mellitus, is a biguanide derivative that is pharmacologically related to phenformin hydrochloride, which was withdrawn from the U.S. market in 1976 (owing to a high incidence of lactic acidosis). Studies support the clinical experience of metformin-induced lactic acidosis as well. Metformin is believed to induce lactic acidosis, especially in the patient with renal insufficiency, by reducing pyruvate dehydrogenase activity and enhancing anaerobic metabolism. A serum creatinine concentration greater than 1.5 mg/dL, congestive heart failure requiring medications, acute or chronic metabolic acidosis, or exposure to iodonated contrast agents within 48 hours are considered absolute contraindications to the drug.

**Salicylates.** Salicylates’ first toxic effect on acid-base balance results from direct stimulation of the respiratory center, increasing minute ventilation and inducing hypocapnia. This is known as the first phase and may last as long as 12 hours. In the early presentation of salicylate toxicity, respiratory alkalosis is often the only acid-base disturbance appreciated. Salicylates can also cause metabolic acidosis by uncoupling oxidative phosphorylation and inhibiting the dehydrogenase enzymes of the Krebs cycle. The second phase of salicylate poisoning is marked by paradoxical aciduria in the presence of continued respiratory alkalosis. This phase may begin within hours and may last 12 to 24 hours. The third phase is marked by dehydration, hypokalemia, and progressive metabolic acidosis. This phase may begin within 4 to 6 hours in infants or more than 24 hours later in adolescents and adults. Treatment...
is supportive, and gastrointestinal decontamination with charcoal may be indicated. Fluid and electrolyte replacement will likely be necessary, and both urinary and serum alkalinization may be of benefit in enhancing elimination and minimizing toxicity.

Normal Anion Gap Metabolic Acidosis

Metabolic acidosis with a normal AG is caused by either an excessive loss of HCO3− or an inability to excrete H+ (see Box 122-4). Any condition that causes excessive loss of intestinal fluid distal to the stomach can cause a normal AG metabolic acidosis. Normal AG metabolic acidosis is primarily a HCO3−-wasting condition and in 95% of cases results from diarrhea. Other possible, although less common, causes include tube drainage and skin fistulae, with loss of HCO3−-rich intestinal, biliary, or pancreatic fluids. Ureterosigmoidostomy (surgical insertion of ureters into the sigmoid colon) produces a hyperchloremic acidosis because of loss of HCO3− in exchange for the reabsorption of Cl−.

Patients with renal failure develop an inability to excrete their dietary H+ load; the severity is proportional to the degree of reduction in the GFR. Patients with renal tubular acidosis type 1 are unable to secrete H+ at the distal tubule, whereas impairment of HCO3− reabsorption at the proximal tubule is the defect in renal tubular acidosis type 2. Calculation of the urinary anion gap (UAG = [Na+ + K+] − Cl−) may be helpful; a negative urinary AG suggests GI loss of HCO3−, whereas a positive urinary AG suggests altered urine acidification, indicating a renal tubule abnormality.

Other causes of normal AG metabolic acidosis include hyperparathyroidism, medications such as carbonic anhydrase inhibitors (e.g., acetazolamide [Diamox], mafenide acetate [Sulfamylon]), spironolactone and cholestyramine, chloride-containing acids ingestion (e.g., NH4Cl, arginine HCl, lysine), renal tubular acidosis, sulfur, CaCl2 and MgCl2 ingestions, and hyperalimentation with excess arginine, lysine, or Cl−.

Physiologic Compensation

The body responds to acidemia by utilizing four buffering systems: (1) extracellular bicarbonate/carbonic acid (HCO3−/H2CO3) system, (2) intracellular blood protein system, and (3) renal and (4) respiratory compensation systems (see Fig. 122-2).

The first two processes minimize the initial [H+], while the kidneys eliminate excessive H+ in the urine, reabsorb HCO3−, and restore acid-base homeostasis. The CNS responds to increased [H+] through direct stimulation of the chemoreceptors in the medulla oblongata, by stimulating the respiratory center. This results in an increase in alveolar ventilation, producing a compensatory elimination of PaCO2 and elimination of excess H+. It may take 12 to 24 hours to achieve a maximal respiratory response to a sustained metabolic acidosis. When the arterial pH is 7.1 or less, the minute ventilation can reach 30 L/min, and at this level of pH, Kussmaul’s respiration and its prominent hyperventilation can be seen.

In response to metabolic acidosis, H+ is excreted by the kidney while HCO3− is reabsorbed. The rate-limiting reaction (the synthesis of H2CO3 from CO2 and H2O) is catalyzed by carbonic anhydrase. Therefore, inhibitors of this enzyme can create a metabolic acidosis by preventing the renal excretion of H+. The excretion of H+ requires buffering with HPO42− or NH3, with NH4+ playing the largest role. This buffering is called titratable acidity. The kidney responds to an increased H+ load by the augmentation of cellular NH3 production and consequently NH4+ excretion.

In summary, H+ is acutely buffered by extracellular and intracellular mechanisms. However, these mechanisms are not potent enough to correct acidosis sufficiently. Acidemia stimulates the CNS ventilatory center, and the PaCO2 is reduced secondary to Kussmaul’s respiration. With continued and chronic acidemia, the kidneys secrete H+ (as NH4+ and H2PO4−) and reabsorb HCO3− in an attempt to neutralize the acidosis.

Management

In treating patients with metabolic acidosis, primary efforts should be directed at restoring their homeostatic mechanisms. The clinician must treat the patient, using laboratory markers only as a guide. Individual therapies are directed toward the particular cause of the acidosis.

Active correction of the pH depends on the severity of the acid-base imbalance, the cause, the patient’s compensatory capabilities, and the potential harm caused by therapy. Most patients with metabolic acidosis do not require aggressive attempts at pH manipulation. For many, the causality is easily discernible, and treatment involves stabilization of homeostatic mechanisms. For example, metabolic acidosis (average pH 7.1) after a seizure resolves within approximately 15 minutes, and the bicarbonate normalizes within 45 to 60 minutes. Rather than administration of sodium bicarbonate (NaHCO3), immediate treatment would involve termination of the seizure activity, maintenance of the airway, and provision for acid-base normalization by ventilatory loss of CO2.

Therapy with NaHCO3 has some inherent complications, and rapid NaHCO3 replacement can result in paradoxical CNS intracellular acidosis, impaired oxygen delivery, hypokalemia, hypocalcemia, “overshoot” alkalosis, hypernatremia, volume overload, and hyperosmolality. Bicarbonate penetration into the CNS across the blood-brain barrier is very slow; consequently, intravenous HCO3− therapy alkalizes the plasma much faster than the CNS. As the serum pH increases, the peripheral chemoreceptors decrease minute ventilation, raising PaCO2 in an attempt to normalize the serum pH. CO2, which rapidly diffuses across the blood-brain barrier, rises intracerebrally, and the CNS becomes more acidemic despite alkalization of the plasma. This inverse reaction is referred to as paradoxical CNS acidosis. Much discussion surrounds this phenomenon and intravenous HCO3− use. Buffer therapy during out-of-hospital cardiac arrest had little to no benefit in one study, regardless of the arterial pH.12 The only prospective, randomized, controlled study was done on hypovolemic rats and failed to demonstrate any difference between the HCO3− and control groups.13 Furthermore, alkali therapy can lead to ECF volume overload (especially in patients with congestive heart failure) and hypokalemia, which may lead to respiratory muscle weakness and inability to hyperventilate if it is severe. Administration of loop diuretics may prevent or treat this complication, but if adequate diuresis cannot be established, emergent dialysis may be necessary.

Because NaHCO3 imparts a significant sodium load on the patient, several low-sodium buffers have been developed. Unfortunately, none has proven to be clinically more efficacious than NaHCO3.14

Because of the inherent complications associated with HCO3− replacement, the rule of thumb is to consider treatment in patients who have pH less than 7.1 with NaHCO3 1 mEq/kg unless the condition of acidemia is expected to be self-limited. For example, many experts do not recommend administration of HCO3− in patients with DKA and pHS as low
Causes of Metabolic Alkalosis

Metabolic alkalosis is produced by conditions that increase $\text{HCO}_3^-$ or reduce $\text{H}^+$. This usually requires either the loss of $\text{H}^+$ or the retention of $\text{HCO}_3^-$. The diagnosis requires knowledge of the $\text{Paco}_2$, because elevation of the plasma $\text{HCO}_3^-$ may be secondary to renal compensation of a chronic respiratory acidosis.

**Etiology**

Metabolic alkalosis is usually caused by an increase in $\text{HCO}_3^-$ reabsorption secondary to volume, potassium, or $\text{Cl}^-$ loss (Box 122-5). Loss of $\text{H}^+$ and $\text{Cl}^-$ from protracted vomiting and nasogastric suctioning can also lead to $\text{HCO}_3^-$ retention. Renal impairment of $\text{HCO}_3^-$ excretion, especially in the setting of alkali therapy, can lead to a significant metabolic alkalosis.

An ECF volume reduction can increase the plasma $\text{HCO}_3^-$ concentration when combined salt and water losses occur, typically in patients using diuretics. This state forces a contraction of the ECF around a constant plasma $\text{HCO}_3^-$, creating a relative excess in $\text{HCO}_3^-$ concentration; this is known as contraction alkalosis.

Metabolic alkalosis can be caused by hypokalemia as $\text{H}^+$ is shifted intracellularly in exchange for the osmotic movement of $\text{K}^+$ extracellularly. There is also an increase in renal $\text{H}^+$ secretion and $\text{HCO}_3^-$ reabsorption. The net effect is ECF alkalinosis with paradoxical intracellular acidosis, which is easily reversed with K+ therapy.

Primary hyperaldosteronism, hyper-reninism, licorice ingestion, Cushing’s syndrome, and congenital adrenal hyperplasia are associated with mineralocorticoid excess. This leads to an increased Na+ reabsorption in the distal tubule with its accompanying $\text{H}^+$ and K+ secretion to maintain electroneutrality.

**Physiologic Compensation**

Although somewhat less predictable, acute compensation of metabolic alkalosis involves the respiratory center, and chronic compensation involves the renal system. During acute compensation, chemoreceptors controlling ventilation respond to an increased pH by inducing hypoventilation, thus increasing $\text{Paco}_2$ and forming $\text{H}^+$, which lowers the pH back to normal. A $\text{Paco}_2$ of greater than 55 mm Hg is unlikely to be caused by simple respiratory compensation of metabolic alkalosis, and this value should alert the clinician to a ventilation disorder complicating the picture. Chronic compensation for metabolic acidosis results from the kidneys excreting excess $\text{HCO}_3^-$ in the urine. In patients with renal failure, impairment in renal $\text{HCO}_3^-$ excretion results in sustained metabolic alkalosis.

**Management**

Clinicians can easily treat the simple loss of $\text{H}^+$ from protracted vomiting or nasogastric suction. For more complicated causes, however, management can be directed by measurement of the urinary $\text{Cl}^-$, which helps classify metabolic alkalosis into saline-responsive or saline-resistant.

**Saline-Responsive Alkalosis**

Patients with saline-responsive alkalosis have a urinary $\text{Cl}^-$ level less than 10 mEq/L. Treatment is directed toward correcting the urinary excretion of $\text{HCO}_3^-$. Administration of NaCl and KCl suppresses both renal acid excretion and renal $\text{HCO}_3^-$ excretion. Administration of NaCl and KCl should be considered for patients with mild to moderate saline-responsive alkalosis. In patients who are severely volume-depleted, consultation for admission and administration of intravenous mineral acids (e.g., arginine monohydrochloride) may be necessary. In edematous states for which saline therapy may be contraindicated, acetazolamide increases the excretion of NaHCO3, treating both the alkalosis and the edema. In renal failure patients, severe metabolic alkalosis should be treated with dialysis.

**Saline-Resistant Alkalosis**

Patients with saline-resistant alkalosis have a urinary $\text{Cl}^-$ level greater than 10 mEq/L. In mineralocorticoid excess, hypokalemia and increased secretion of aldosterone lead to excessive renal excretion of $\text{H}^+$ and a reabsorption of $\text{HCO}_3^-$. Treatment can be successful with K+ replacement by reversing the intracellular shift of $\text{H}^+$. This reduction of cellular $\text{H}^+$ also enhances $\text{HCO}_3^-$ excretion. Additional therapy can be directed toward reducing mineralocorticoid activity (e.g., administering spironolactone, an aldosterone antagonist).

**MIXED ACID-BASE DISORDERS**

Double and triple primary acid-base disturbances are common. Traditionally, mixed disorders have been difficult to evaluate in the emergency department. However, recent literature pro-
Step 1 involves measuring the pH. It is necessary to first assess whether the patient has an acidemia (pH < 7.36) or alkalemia (pH > 7.44). The human body almost never fully compensates for any primary acid-base disturbance except for chronic respiratory alkalosis.

Step 2: Is the primary disturbance respiratory or metabolic? Step 3 requires the clinician to calculate the AG. Box 122-3 lists possible causes of an AG greater than 15 mEq/L, and Box 122-4 lists possible causes for a case in which the AG is normal but the patient has a metabolic acidosis.

Step 4 involves calculating the delta gap (ΔG = deviation of AG from normal – deviation of HCO₃⁻ from normal) to help resolve the possibility of a mixed acid-base disorder or further differentiate an elevated AG metabolic acidosis.

Values for the AG are all gaussian, and therefore the mean value should be near zero. An expected normal range for the AG would be 0 ± 6. A positive ΔG (+6 or greater) is almost always caused by high AG acidosis and a primary metabolic alkalosis. DKA or AKA with severe vomiting, lactic acidosis in the setting of chronic diuretic use, and renal disease with vomiting are clinical examples.

A negative ΔG (−6 or less), on the other hand, can be of varied clinical representation. Most often there is either a mixed high AG and normal AG acidosis, or a high AG acidosis with chronic respiratory alkalosis and a compensating hyperchloremic acidosis. Clinically, these patients often have severe underlying metabolic disease with ongoing toxic ingestion (e.g., profound hypermagnesemia, hyponatremia, or hypercalcemia in patients with lithium toxicity) or chronic lung disease, acute lactic acidosis, and furosemide use. Other relationships in these disorders can also assist in rapid interpretation of mixed acid-base disturbances (Box 122-6).

Step 5 asks whether the respiratory disturbance (if there is one) is acute or chronic. If acute, for each change in PCO₂ of 10 mm Hg, the pH changes by 0.08 in the opposite direction. If chronic, for each change in PCO₂ of 10, the pH changes by 0.03 in the opposite direction.

Step 6 involves determining if the respiratory system has compensated fully when the primary disturbance is a metabolic acidosis. Using Winter’s formula (PCO₂ = 1.5 (HCO₃⁻) + 8 ± 2), you can calculate the degree of compensation.

Values for the AG are all gaussian, and therefore the mean value should be near zero. An expected normal range for the AG would be 0 ± 6. A positive ΔG (+6 or greater) is almost always caused by high AG acidosis and a primary metabolic alkalosis. DKA or AKA with severe vomiting, lactic acidosis in the setting of chronic diuretic use, and renal disease with vomiting are clinical examples.

A negative ΔG (−6 or less), on the other hand, can be of varied clinical representation. Most often there is either a mixed high AG and normal AG acidosis, or a high AG acidosis with chronic respiratory alkalosis and a compensating hyperchloremic acidosis. Clinically, these patients often have severe underlying metabolic disease with ongoing toxic ingestion (e.g., profound hypermagnesemia, hyponatremia, or hypercalcemia in patients with lithium toxicity) or chronic lung disease, acute lactic acidosis, and furosemide use. Other relationships in these disorders can also assist in rapid interpretation of mixed acid-base disturbances (Box 122-6).

Step 5 asks whether the respiratory disturbance (if there is one) is acute or chronic. If acute, for each change in PCO₂ of 10 mm Hg, the pH changes by 0.08 in the opposite direction. If chronic, for each change in PCO₂ of 10, the pH changes by 0.03 in the opposite direction.

Step 6 involves determining if the respiratory system has compensated fully when the primary disturbance is a metabolic acidosis. Using Winter’s formula (PCO₂ = 1.5 (HCO₃⁻) + 8 ± 2), you can calculate the degree of compensation.

Mixed acid-base disturbances typically result from compensation failure, excessive compensation, or more than one disease process. Examples of compensation failures resulting in metabolic acidosis and respiratory acidosis include: cardiac arrest patients, chronic obstructive pulmonary disease patients with respiratory failure and hypoxemia, and hypoventilation and acidosis-causing toxins. Metabolic alkalosis and respiratory alkalosis may result from compensation failure in patients who are pregnant with hyperemesis and in patients with postoperative pain and vomiting. Patients with salicylate overdose, pulmonary edema, sepsis, and hepatic failure may exhibit excessive compensation and a combined metabolic acidosis and respiratory alkalosis that results in a near neutral pH. Superimposed metabolic acidosis and alkalosis may also be present in patients with excessive compensation due to vomiting in association with DKA or AKA. In the alcoholic patient with AKA you may find a triple acid-base disturbance as a result of vomiting (metabolic alkalosis), withdrawal (respiratory alkalosis), and the AKA (metabolic acidosis). A thorough history and physical examination can be especially important in prompting the clinician to consider a complicated acid-base disturbance.
Figure 122-3. Algorithm for acid-base calculation.
- Changes in serum pH are dealt with by three compensatory systems: (1) the physiologic buffers, (2) the lungs, and (3) the kidneys.
- HCO$_3^-$ is present in large quantities and can be controlled by the lungs and kidneys, making it the major contributor to the maintenance of acid-base balance and the primary system to handle the acute load of organic acidemia.
- Respiratory acidosis is defined as decreased pH that results from pulmonary CO$_2$ retention. This CO$_2$ retention leads to excess H$_2$CO$_3$ production and acidemia.
- Increased minute ventilation is the primary cause of respiratory alkalosis, characterized by decreased Paco$_2$ and increased pH.
- Metabolic acidosis can be caused by one of three mechanisms: (1) increased production of acids, (2) decreased renal excretion of acids, or (3) loss of alkali. The causes of metabolic acidosis can be divided into those that create an elevation in the AG and those that do not.
- Metabolic alkalosis is usually caused by an increase in HCO$_3^-$ reabsorption secondary to volume, potassium, or Cl$^-$ loss.
- Contraction alkalosis can result from extracellular volume reduction, with a consequent increase in the plasma HCO$_3^-$ concentration, when combined salt and water losses occur. This typically occurs in patients using diuretics.
- Determination of a mixed acid-base disorder requires knowledge of the pH, calculation of the AG, and calculation of the $\Delta$G.

Chapter 123  Electrolyte Disturbances

Michael A. Gibbs and Vivek S. Tayal

Perspective

An electrolyte is any substance that has free ions and therefore can conduct an electrical charge when in solution. The principal electrolytes in human physiology are sodium (Na⁺), potassium (K⁺), calcium (Ca²⁺), magnesium (Mg²⁺), chloride (Cl⁻), and hydrogen phosphate (HPO₄²⁻). Gradients of electrolytes between the intracellular and extracellular spaces are carefully maintained and are responsible for the electrical conduction required for muscles and nerves to function. The electrolyte concentrations of the body are maintained principally through kidney function, but also through action of hormones such as antidiuretic hormone, aldosterone, and parathyroid hormone. Dysfunction of any of these mechanisms or even severe physiologic stress, can disrupt electrolyte balance and result in a life-threatening emergency.

Sodium

Normal Physiology

Since electrolytes exist in solution in the human body, fluid balance and electrolyte balance are linked, and under hormonal control. Water makes up approximately 60% of body weight and is distributed in three compartments: the intracellular space, the interstitial space, and the intravascular space. The intracellular space makes up approximately two thirds of total body water, with the remaining one third in the interstitial and intravascular spaces. The concentration of sodium [Na⁺], the predominant extracellular cation, governs the movement of water among these three compartments. When the extracellular [Na⁺] decreases, water shifts to the intracellular space to restore osmotic equilibrium. When the extracellular [Na⁺] rises, water shifts out of the intracellular space. Under normal conditions, Na⁺ leaks passively into cells down a concentration gradient and is transported back out of the cell by the sodium-potassium adenosine triphosphatase (Na⁺-K⁺ ATPase) pump.

Na⁺ homeostasis and water balance are under the hormonal regulation of the renin-angiotensin system and antidiuretic hormone, respectively. Renin, an enzyme produced by the kidney, is released in response to decreases in circulating intravascular volume. Renin catalyzes the production of angiotensin I, which is then converted to angiotensin II in the lung. Angiotensin II stimulates the production of aldosterone, a mineralocorticoid hormone produced by the zona glomerulosa of the adrenal glands. Aldosterone enhances Na⁺ reabsorption and K⁺ excretion in the distal nephron.

Antidiuretic hormone (ADH, vasopressin, arginine vasopressin) is synthesized in the hypothalamus and secreted from the posterior pituitary. ADH is released primarily in response to rises in serum osmolality but also to decreases in intravascular volume or arterial pressure. Volume depletion is the most potent stimulus for ADH production, and with decreases in plasma volume, ADH may be secreted even in the face of hypotonicity. ADH enhances renal water reabsorption by increasing tubular water permeability. Other factors that may stimulate ADH release include angiotensin, catecholamines, opiates, caffeine, hypoglycemia, hypoxia, and stress.

Hyponatremia

Principles of Disease

Hyponatremia is defined as a serum [Na⁺] of less than 135 mEq/L. Hyponatremia can be classified into three categories based on the patient’s clinical volume status: (1) hypovolemic hyponatremia, (2) euvolemic hyponatremia, and (3) hypervolemic hyponatremia (Box 123-1). When assessing the patient with a low serum Na⁺ level, it is also important to consider the possibility of sampling errors (e.g., phlebotomy from a venous site proximal to an infusion of hypotonic solution), as well as pseudohyponatremia and redistributive hyponatremia.

Pseudohyponatremia. Pseudohyponatremia refers to a falsely low serum Na⁺ measurement in patients whose plasma contains excessive protein or lipid. The relative percentage of water in plasma is reduced. Flame photometry, which determines Na⁺ content per unit of plasma, shows an artificially low Na⁺ level, although both the total Na⁺ content and the serum osmolarity remain within the normal range. Measurement of the serum Na⁺ by direct potentiometry avoids this problem.

Redistributive Hyponatremia. Redistributive hyponatremia is caused by osmotically active solutes in the extracellular space that draw water from the cell, diluting the serum [Na⁺]. Common situations causing such hyperosmolar states include hyperglycemia (e.g., diabetic ketoacidosis [DKA]) and parenteral administration of mannitol or glycerol for the management of intracranial hypertension or glaucoma. The measured serum Na⁺ in patients with hyperglycemia can be corrected by adding approximately 1.6 mEq/L for every 100-mg/dL rise in the serum glucose over 100 mg/dL.

Hypovolemic Hyponatremia. Hypovolemic hyponatremia results from the loss of water and Na⁺ with a greater relative loss of Na⁺. Typical causes include vomiting, diarrhea, gastrointestin-
Causes of Hyponatremia

Hypervolemic hyponatremia results when Na⁺ is retained but retention of water exceeds that of Na⁺. This is seen in edematous states such as congestive heart failure, hepatic cirrhosis, and renal failure. In these conditions, decreased effective renal perfusion causes the secretion of both ADH and aldosterone. This leads to increased tubular reabsorption of both Na⁺ and water, decreased delivery of water to the distal nephron, and inability to produce hypotonic urine.

Euvolemic Hyponatremia. The many causes of euvolemic hyponatremia include the syndrome of inappropriate secretion of ADH (SIADH), defined as the secretion of ADH in the absence of an appropriate physiologic stimulus. Its hallmark is an inappropriately concentrated urine despite the presence of a low serum osmolality and a normal circulating blood volume. Causes of SIADH include central nervous system (CNS) disorders, pulmonary disease, drugs, stress, pain, and surgery (Box 123-2). Before the diagnosis of SIADH can be confirmed, other potential causes of euvolemic hyponatremia (e.g., hypoadrenalinism, hypothyroidism, renal failure) should be ruled out. Psychogenic polydipsia is a rare cause of euvolemic hyponatremia. This is most often seen in patients with psychiatric disorders who consume large volumes of water, usually in excess of 1 L/hr, overwhelming the capacity of the kidneys to excrete free water in the urine. In contrast to SIADH, the urine in patients with psychogenic polydipsia is maximally dilute.

Hypovolemic Hyponatremia. Hypovolemic hyponatremia results when Na⁺ is retained but retention of water exceeds that of Na⁺. This is seen in edematous states such as congestive heart failure, hepatic cirrhosis, and renal failure. In these conditions, decreased effective renal perfusion causes the secretion of both ADH and aldosterone. This leads to increased tubular reabsorption of both Na⁺ and water, decreased delivery of water to the distal nephron, and inability to produce hypotonic urine.

Clinical Features

The primary symptoms of hyponatremia are CNS symptoms, including lethargy, apathy, confusion, disorientation, agitation, depression, and psychosis. Focal neurologic deficits, ataxia, and seizures have been reported. Other nonspecific signs and symptoms include muscle cramps, anorexia, nausea, and weakness.

The signs and symptoms of hyponatremia depend on the rapidity with which the serum [Na⁺] declines, as well as on its absolute level. The acutely hyponatremic patient is almost always symptomatic when the serum Na⁺ level falls below 120 mEq/L, whereas patients with chronic hyponatremia may tolerate much lower levels. Very young and very old patients typically develop symptoms with lesser decreases in the serum Na⁺ level.

Diagnostic Strategies

The urinary [Na⁺] can be a useful tool in the assessment of the patient with hyponatremia. Patients with hypovolemic hyponatremia caused by renal Na⁺ wasting typically have an inappropriately high urinary [Na⁺] (>20 mEq/L); those with extrarenal Na⁺ wasting and intact renal Na⁺-conserving mechanisms have a low urinary [Na⁺] (<10 mEq/L). Patients with euvoletic hyponatremia generally have a urinary Na⁺ concentration greater than 20 mEq/L. Patients with hypervolemic hyponatremia caused by congestive heart failure or cirrhosis typically have a [Na⁺] below 10 mEq/L, and those with renal failure have a concentration above 20 mEq/L.

Management

Because tolerance for hyponatremia is highly variable, treatment should be guided by the severity of symptoms, the estimated duration of illness, and the patient’s volume status rather than by the serum Na⁺ level alone. Severe neurologic dysfunction and seizures are an indication for immediate treatment. Patients with signs of shock or symptomatic fluid overload also require rapid intervention. Because individuals with acute hyponatremia typically develop more prominent symptoms than those with chronic hyponatremia and are more tolerant of rapid correction of Na⁺ deficits, vigorous treatment is a
Hyponatremia.

The cornerstone of therapy for patients with hyponatremia and a normal total circulating volume can usually have free water intake restricted while the cause of the hyponatremia is determined and specific treatment for the underlying disorder is begun. Significantly, patients with SIADH who are given normal saline may actually experience a further decrease in the serum Na⁺ as free water is retained and a hypertonic urine is excreted. Lithium and demeclocycline, which inhibits the action of ADH, can also be used in the treatment of SIADH.

Euvolemic Hyponatremia. Patients with hyponatremia and a normal total circulating volume can usually have free water intake restricted while the cause of the hyponatremia is determined and specific treatment for the underlying disorder is begun. Significantly, patients with SIADH who are given normal saline may actually experience a further decrease in the serum Na⁺ as free water is retained and a hypertonic urine is excreted. Lithium and demeclocycline, which inhibits the action of ADH, can also be used in the treatment of SIADH.

Symptomatic Hyponatremia. Patients with severely symptomatic hyponatremia (e.g., seizures) may require administration of 3% saline (513 mEq of Na⁺/L). In general, the serum Na⁺ level should not be corrected to above 120 mEq/L or increased by more than 10 mEq/L in a 24-hour period. The rate of correction of hyponatremia should be dictated by the rapidity of its onset. Acute hyponatremia can be corrected at rates of up to 1 to 2 mEq/L/hr, and chronic hyponatremia should be corrected at a rate not greater than 0.5 mEq/L/hr. Hypertonic saline should be administered through a controlled intravenous (IV) infusion, paying careful attention to fluid input and output and frequently assessing serum electrolytes. The approximate required dose of hypertonic saline can be calculated with the following formula:

\[
(\text{Desired Na⁺} - \text{measured Na⁺}) \times (0.6) \times (\text{weight in kg}) = \text{mEq Na⁺ administered}
\]

Overly aggressive correction of the serum Na⁺ level can have serious consequences. Central pontine myelinolysis, also known as cerebral demyelination, involves the destruction of myelin in the pons and is thought to result from rapid elevation of the serum Na⁺. Patients may develop cranial nerve palsies, quadriplegia, or coma. Central pontine myelinolysis is more likely to occur in patients with chronic hyponatremia than in those with acute hyponatremia. Most cases have been associated with rapid correction of serum Na⁺ in alcoholic, malnourished, and elderly patients, although it has also been described in otherwise healthy patients.

Hypernatremia

Principles of Disease

Hypernatremia is defined as a serum [Na⁺] above 145 mEq/L. Patients at the extremes of age and those with chronic disorders are particularly vulnerable. Hypernatremia is most often the result of a decrease in free water because of either reduced water intake or increased water loss. Less often, hypernatremia is caused by an increase in total Na⁺ (Box 123-3). This classification scheme helps in identifying the underlying cause and guiding therapy.

Reduced water intake may be the result of limited access, inability to tolerate oral fluids, defective thirst mechanisms, or depressed mentation.

Increased water loss can occur through several different organ systems, including the gastrointestinal tract, skin, respiratory tract, or kidney. Gastrointestinal losses can occur from protracted diarrhea, vomiting, nasogastric tube suction, or third spacing. Renal causes of water loss include osmotic diuresis (e.g., hyperglycemia, mannitol administration) and renal tubular concentrating defects. Diabetes insipidus (DI) results in the loss of large amounts of dilute urine from the loss of concentrating ability in the distal nephron. DI may be central (lack of ADH secretion from the pituitary) or nephrogenic (lack of responsiveness to circulating ADH) (Box 123-4). Central DI is seen with CNS disease or surgery involving the hypothalamus and pituitary. Common mechanisms include stroke, infection, tumor, trauma, and systemic diseases. Nephrogenic DI can be caused by congenital disease, renal failure, sickle cell anemia, hypercalcemia, hypokalemia, and certain drugs, including lithium, cisplatin, amphotericin B, aminoglycosides, and demeclocycline. With a normal thirst mechanism and access to water, DI patients are generally able to maintain near-normal serum levels.6,7 However, they quickly become hypernatremic when removed from a water source, and any sodium-containing IV fluids will exacerbate the problem.

Excessive Na⁺ intake, accidentally, intentionally, or iatrogenically, can cause hypernatremia in the absence of corresponding intake of water. Because the kidney can usually...
excrete an increased Na⁺ load effectively, most cases are seen in patients with renal insufficiency. Examples include hypertonic enteral or parenteral nutritional fluids, saline absorption, administration of large amounts of sodium bicarbonate, seawater drowning, and salt ingestion. The administration of ticarcillin and carbencillin, which contain large amounts of NaCl, is another potential cause.

Clinical Features
In cases of hypernatremia, free water is lost in excess of Na⁺, so patients may be significantly dehydrated before signs of volume depletion are evident. Total free water deficits are often underestimated in this setting. Common symptoms include anorexia, nausea, vomiting, fatigue, and irritability. Physical findings include lethargy, confusion, stupor, coma, muscle twitching, hyper-reflexia, spasticity, tremor, ataxia, or focal findings such as hemiparesis or extensor-plantar reflexes.

Management

**Hypovolemic Hypernatremia.** The primary goals in the emergency management of hypovolemic hypernatremia are to restore volume deficits and to maintain organ perfusion. Treatment should be initiated with an infusion of isotonic saline solution (0.9%). Once the patient is hemodynamically stable, the remaining free water deficits can be replaced.

**Euvolemic Hypernatremia.** Euvolemic hypernatremic patients may have had either hypotonic fluid losses (e.g., with DI) or hypertonic fluid losses from increased insensible fluid loss. Patients with DI generally have a low urine specific gravity (<1.005) and low urine osmolality. The DI is usually the result of a previously recognized disorder, and patients can usually maintain their serum osmolality if they have access to water. Treatment is with oral fluids or 0.45% saline. Patients with central DI require parenteral or intranasal vasopressin. The response to vasopressin can be monitored by checking urine osmolality, urine specific gravity, and serum electrolytes.

**Hypervolemic Hypernatremia.** The treatment of hypervolemic hypernatremia should focus on increasing renal Na⁺ excretion while maintaining free water intake. A strategy of diuretic administration (e.g., furosemide) followed by infusion of hypotonic fluids gradually restores the serum Na⁺ to the normal range. Dialysis may be needed for patients with renal failure.

**Symptomatic Hypernatremia.** Patients with acute hypernatremia usually tolerate rapid correction of free water deficits. On the other hand, aggressive treatment of chronic hypernatremia with hypotonic fluids may result in life-threatening complications. It is recommended that in this setting free water deficits be corrected over at least a 48-hour period. When hypernatremia develops over days, brain cells produce osmotic substances (idiogenic osmoles) that hold water in the cell and help maintain cellular volume and tonicity. Overzealous administration of hypotonic fluids may cause rapid shifts of water into brain cells, cellular swelling, and cerebral edema.

Assuming only loss of free water, the free water deficit can be calculated as follows:

\[
\text{FW deficit} = 0.6 \times \text{weight (kg)} \times \left( \frac{\text{current Na}^+}{4} - 1 \right)
\]

### POTASSIUM

**Normal Physiology**

The relative concentrations of potassium [K⁺] in the intracellular fluid and extracellular fluid are the major determinants of the normal osmotic and electrochemical gradients of all living cells. Precisely controlled transcellular movement of K⁺ in excitable tissues is required for neuronal transmission, cardiac conduction, and excitation-contraction coupling. K⁺ is also important for acid-base balance; the exchange of K⁺ and hydrogen ions H⁺ across the cell membrane serves as a first-line buffering system during acute acidosis and alkalosis. K⁺ is also required for intracellular glucose metabolism, oxidative phosphorylation, and protein synthesis.

The adult human body contains between 2500 and 3500 mmol of K⁺, 98% of which is found in the intracellular compartment. For this reason, the serum K⁺ level is not an accurate indicator of total K⁺ stores. The normal range of the serum [K⁺] is 3.5 to 5.0 mEq/L.

Ingested potassium is absorbed in the small intestine through passive transport mechanisms. Renal excretion is the major route of K⁺ elimination; less than 8% of losses occur in the feces and sweat. In the kidneys, 90% of the filtered load of K⁺ is reabsorbed in the proximal tubule, and K⁺ balance is determined by the handling of the cation in the distal nephron. The Na⁺-K⁺ ATPase pump transports K⁺ from the serum into distal tubular cells against a concentration gradient. K⁺ then moves passively into the tubular lumen in exchange for Na⁺ and is excreted in the urine. When the serum K⁺ level increases, pump activity increases and renal K⁺ excretion increases. When the serum K⁺ level falls, the pump is less active and excretion decreases. Aldosterone also controls K⁺ homeostasis. Increased aldosterone release causes retention of Na⁺ and excretion of K⁺ at the distal tubule. Decreased aldosterone release or inhibition of aldosterone (by drugs such as angiotensin-converting enzyme inhibitors or spironolactone) promotes K⁺ retention. Acidosis and alkalosis also affect renal K⁺ handling. Acidosis promotes secretion of H⁺ into the distal tubule, with retention of K⁺, and alkalosis tends to favor renal K⁺ excretion.

The serum K⁺ level depends on the distribution of K⁺ between the serum and cells, as well as the balance between...
K⁺ intake and excretion. Acute decreases in the plasma pH cause K⁺ to shift out of the cell in exchange for H⁺. Conversely, alkalosis promotes movement of extracellular K⁺ into the cell in exchange for intracellular H⁺. In general, a change of 0.1 pH unit causes an inverse change of approximately 0.6 mEq in the serum K⁺. Respiratory acid-base disturbances affect serum K⁺ in the same manner as metabolic changes, but not as predictably. K⁺ levels are also influenced by hormones and hormone receptor stimulation. Insulin increases cellular K⁺ uptake by means of the Na⁺-K⁺ ATPase pump. Insulin release is stimulated by hyperglycemia, and hypokalemia inhibits insulin release. Alpha-adrenergic stimulation promotes hyperkalemia, and beta-stimulation causes uptake of K⁺ into cells.⁹

Hypokalemia

Principles of Disease

Hypokalemia is relatively common, although life-threatening hypokalemia is much less common.¹⁰ Hypokalemia may be the result of decreased K⁺ intake, increased K⁺ excretion, or transcellular K⁺ shifts (Box 123-5).

Hypokalemia resulting from decreased dietary intake is rare. However, when poor intake is combined with other factors (e.g., vomiting or diarrhea, high insulin or aldosterone levels), severe hypokalemia can result. Patients suffering from prolonged starvation may become hypokalemic when they are fed because insulin secretion and increased cellular uptake cause K⁺ to move into cells.

Pronounced renal or gastrointestinal K⁺ losses can result in hypokalemia. Diuretic therapy, the most common cause of hypokalemia in clinical practice, increases Na⁺ delivery to the distal tubule, promoting K⁺ excretion. Associated volume depletion and high levels of aldosterone cause K⁺ and H⁺ excretion and may worsen hypokalemia. In addition, alkalosis from H⁺ excretion promotes cellular K⁺ uptake, further lowering the serum K⁺ level.¹⁰

Other disorders can cause significant renal K⁺ loss. These include osmotic diuresis, high mineralocorticoid states, Mg²⁺ depletion, and high urinary concentrations of anions such as penicillin. Intrinsic renal causes of K⁺ loss include renal tubular acidosis (RTA), chronic interstitial disease, and drugs that affect tubular potassium reabsorption. RTA type 1 is caused by a defect in H⁺ secretion in the distal tubule, and RTA type 2 is associated with a similar defect in the proximal tubule. In both cases, increased K⁺ excretion at the distal tubule is the result. Other causes of increased renal K⁺ loss include hypercalcemia, toxins (e.g., cisplatin, amphotericin B, aminoglycosides), leukemia, interstitial nephritis, and postobstructive diuresis.

Primary hyperaldosteronism (Conn’s syndrome), which is typically caused by adrenal adenoma, is characterized by hypertension and hypokalemia.¹¹ Secondary hyperaldosteronism, due to increased renin release, causes hypokalemia in the face of volume depletion as K⁺ is exchanged for Na⁺ at the distal tubule. In Bartter’s syndrome, a disorder causing hyperplasia of the juxtaglomerular apparatus and hyper-reninism, patients typically have weakness and hypokalemia.

Gastrointestinal losses of K⁺ occur in patients with protracted vomiting and diarrhea. Vomiting itself does not cause K⁺ loss; rather, hypokalemia results from hypovolemia, secondary hyperaldosteronism, and alkalosis. Diarrhea can cause

hypokalemia from losses in the stool and secondary hyperaldosteronism. Patients with villous adenomas classically have tremendous losses of K+ from diarrheal fluid.

Loss of K+ from the skin in sufficient quantities to cause hypokalemia is unusual unless the patient has experienced extreme sweating or is a victim of extensive burns or toxic epidermal necrolysis. Hypokalemia may result from transcellular K+ shifts, most often because of alterations in acid-base balance. Acidosis causes K+ to move out of the cell in exchange for H+, and the reverse is true for alkalosis. Although acidosis is typically associated with hyperkalemia, acidosis may also be associated with hypokalemia in the presence of increased urinary K+ losses (e.g., DKA). Beta-receptor stimulation is another common cause of hypokalemia resulting from transcellular shifts. In the emergency department, this is most likely to occur in the patient receiving large doses of beta-agonists for the treatment of asthma or chronic obstructive pulmonary disease.12,13

The periodic paralyses are associated with varying serum K+ levels, including hypokalemia. They often are associated with thyroid disease and are distinguished by symmetrical proximal weakness.14

Clinical Features

Hypokalemia can affect the neuromuscular, cardiovascular, gastrointestinal, and renal systems, as well as acid-base balance. Signs and symptoms of neuromuscular dysfunction usually occur when the serum K+ level is less than 2.5 mEq/L.15 CNS signs include lethargy, depression, irritability, and confusion. Peripheral manifestations include paresthesias, fasciculations, myalgias, and prominent muscle weakness. Muscular paralysis can occur with serum levels below 2.0 mEq/L.

Patients with severe hypokalemia may develop rhabdomyolysis because of impaired energy metabolism, membrane pump dysfunction, and local muscle ischemia.16 K+ is released from injured muscle, so the responsible hypokalemia may not be clinically evident, with serum levels normal or even elevated.

Cardiovascular manifestations of hypokalemia include palpitations, postural hypotension, ectopy, and dysrhythmias. First- and second-degree heart block, atrial fibrillation, paroxysmal ventricular contractions, ventricular fibrillation, and asystole have all been reported. The electrocardiogram (ECG) shows flattening of T waves, ST segment depression, and the appearance of U waves.16

Hypokalemia impairs intestinal smooth muscle activity and may cause nausea, vomiting, and abdominal distention. Severe hypokalemia may produce paralytic ileus.10 The renal manifestations of hypokalemia include polyuria, polydipsia, and impaired ability to concentrate urine or excrete an acid load.

The effect of hypokalemia on acid-base balance is to promote metabolic alkalosis. In response to a low serum K+ level, K+ moves out of the cell in exchange for H+, causing an extracellular alkalosis and an intracellular acidosis. In response to the drop in intracellular pH, renal tubular cells excrete H+, leading to paradoxical aciduria and exacerbating the extracellular alkalosis.

Management

Because K+ is an intracellular cation, a low serum K+ level reflects a much greater total K+ deficit. In the absence of acute shifts caused by acid-base disturbances, a decrease of the serum K+ by 1.0 mEq/L may reflect a 370-mEq deficit of total K+. Because up to 50% of administered K+ is excreted in the urine, correction of large deficits may require several days.

Whenever possible, oral therapy is preferable to IV therapy because the risk of hyperkalemia is significantly less. However, patients with prominent symptoms (e.g., dysrhythmias) and those who are unable to tolerate oral supplements should receive IV K+ replacement. IV K+ is usually given at a rate of 10 to 20 mEq/hr, but larger doses can be given to patients with severe depletion or severely symptomatic hypokalemia (e.g., respiratory muscle weakness). Doses greater than 20 mEq/hr should be given in a monitored setting through a large-bore peripheral venous catheter or a central venous access site.17

Burning at the infusion site is the most common side effect of IV K+ administration. Slowing the rate of infusion usually decreases venous irritation. The most important potential risk of IV K+ administration is acute hyperkalemia, which is most likely in patients with renal insufficiency. If dysrhythmias (e.g., frequent premature ventricular contractions, heart block, tachycardia, widening of the QRS complex) develop, the K+ infusion should be discontinued immediately.

Oral potassium is preferred for mild hypokalemia. Several oral preparations are available in liquid or tablet form. Although liquid preparations are typically better absorbed, matrix tablets are often better tolerated. Hypokalemia can be effectively corrected with oral supplements, and large amounts of oral potassium can be given to increase serum levels rapidly.

Potassium can be given as the chloride salt in most patients. Potassium phosphate, rather than potassium chloride, can be given if there is associated hypophosphatemia (e.g., in DKA). Patients with distal RTA should be treated with potassium bicarbonate, potassium citrate, or potassium gluconate, which provide both K+ and base equivalents. The hypokalemia of proximal RTA may be better treated with potassium chloride because the administered base cannot be reabsorbed well proximally and can obligate K+ loss when it reaches the distal tubule.

Hyperkalemia

Principles of Disease

Hyperkalemia may be the result of increased K+ intake, enhanced K+ absorption, impaired K+ excretion, or shifts of K+ out of cells into the serum (Box 123-6).

When faced with a report of a high serum K+ level, the emergency physician should first consider the possibility of laboratory error. Hemolysis during phlebotomy, as can occur when blood is obtained with a small needle or sampled in a high-vacuum tube, releases K+ into the sample and causes a spuriously high K+ measurement. Laboratory technicians usually note the presence of pink serum, indicating hemolysis. Pseudohyperkalemia can also occur when K+ is released from platelets in patients with severe thrombocytosis or from leukocytes in patients with extreme leukocytosis.19

Hyperkalemia rarely results from increased K+ intake. This is more common when K+ supplements are inadvertently taken by patients with renal insufficiency or in those taking a K+-sparring diuretic or an angiotensin-converting enzyme inhibitor.18 Parenteral medications such as penicillin and carbencillin, as well as transfused blood, also contain significant amounts of K+ and can precipitate hyperkalemia.

Renal insufficiency (i.e., decreased GFR), defects in tubular K+ secretion, or hypoadosteronism can cause hyperkalemia. As GFR decreases to approximately 5 to 15 mL/min, excretion of the normal daily K+ load is impaired. Defects in tubular K+ excretion are associated with a number of conditions. Hypoadosteronism may be the result of causes as varied as RTA type
Immediate antagonism of K+.

Causes of Hyperkalemia

- Sodium bicarbonate infusion promotes a Gluconate.

Cellular uptake of K+ or ATPase pump, with resultant hyperkalemia in severe cases.

cause of transcellular K+ such as exercise, infection, and diet. Drugs may also be the cause of hyperkalemia caused by cellular efflux of K+ associated with stressors such as exercise, infection, and diet. Drugs may also be the cause of transcellular K+ shifts.

Hyperkalemia causes transient K+ efflux because of depolarization of the muscle cell membrane. High-dose trimethoprim-sulfamethoxazole has also been implicated in hyperkalemia, especially with concomitant renal insufficiency. 4, 15

Clinical Features

Cardiovascular and neurologic dysfunction is the primary manifestation of hyperkalemia. 18 Patients may have a variety of dysrhythmias, including second- and third-degree heart block, wide-complex tachycardia, ventricular fibrillation, and even asystole. The ECG can provide valuable clues to the presence of hyperkalemia. As K+ levels rise, peaked T waves are the first characteristic manifestation. Further rises are associated with progressive ECG changes, including loss of P waves and widening and slurring of the QRS complex. Eventually, the tracing assumes a sine wave appearance, followed by ventricular fibrillation or asystole. Concomitant alkalosis, hypernatremia, or hypercalcemia antagonizes the membrane effects of hyperkalemia and may delay or diminish the characteristic ECG findings.

Neuromuscular signs and symptoms of hyperkalemia include muscle cramps, weakness, paralysis, paresthesias, tetany, and focal neurologic deficits, but these are rarely specific enough to suggest the diagnosis in themselves. 15, 16

Management

The treatment of hyperkalemia includes cardiovascular monitoring, administration of calcium chloride or gluconate to treat hemodynamic instability, initiation of measures to lower serum K+, and correction of the underlying cause.

All patients with suggested hyperkalemia should be on a cardiac monitor, and attention should be paid to the morphology of the T waves and QRS complex. Peaked T waves, loss of P waves, slurring of the QRS, and second- or third-degree heart block all suggest hyperkalemia and are indications for prompt therapy. Treatment of the hyperkalemia is directed toward antagonism of the membrane effects of hyperkalemia, promotion of transcellular K+ shifts, and removal of K+ from the body.

Calcium Chloride or Gluconate. Immediate antagonism of K+ at the cardiac membrane is achieved with IV administration of calcium chloride or gluconate. This is indicated in patients with unstable dysrhythmia or hypotension. Several ampules of calcium (10 mL of 10% solution) may be required. 14, 15 Because of the brief duration of action (approximately 20–40 minutes), other measures should also be instituted promptly. 18

Sodium Bicarbonate. Sodium bicarbonate infusion promotes a shift of K+ into cells. One ampule (44 mEq) should be given by slow IV push over 5 to 15 minutes. The duration of action is approximately 2 hours. Sodium bicarbonate should be used with caution when hypertonicity, volume overload, or alkalosis poses a risk to the patient. Bicarbonate therapy is less efficacious than insulin or albuterol. 21, 22

Glucose and Insulin. Cellular uptake of K+ can also be induced with a regimen of IV glucose and insulin. Regular insulin (10–20 U) can be given by bolus infusion. Dextrose should be administered to euglycemic and diabetic patients with a blood glucose level below 250 mg/dL to prevent hypoglycemia. This combination lasts 4 to 6 hours. 18 Rapid infusion of hypertonic glucose solution may transiently exacerbate hyperkalemia by its osmotic effect on cells.

Beta-agonists. The known effect of beta-agonists to cause movement of K+ into cells can be harnessed to lower the...
Hormone treatment of any underlying causative disorder should be initiated at the same time as therapy for hypercalcemia. The skeleton acts as a calcium pool that buffers acute changes in serum calcium. When the serum calcium level falls, PTH stimulates an increase in bone turnover and the release of calcium into the serum. A rise in serum calcium suppresses PTH production and causes the release of calcitomin. Calcitonin decreases osteoclastic activity and enhances skeletal deposition of calcium.

The serum calcium level reflects the net outcome of several processes. On one hand, intestinal absorption and bone resorption add calcium to the blood; on the other, calcium is lost from the blood by renal excretion, skeletal uptake, or abnormal deposition in soft tissues. A decrease in the serum Ca²⁺ activates the PTH–vitamin D system to increase the entry of calcium into the blood from the bone and gastrointestinal tract. A rise in the serum calcium level suppresses the PTH–vitamin D system and increases the release of calcitonin, which decreases calcium entry into the blood.

Many hospital laboratories measure total serum calcium concentrations, which is a combination of both Ca²⁺ and calcium that is bound to proteins. Normal value of total serum calcium ranges from 8.5 to 10.5 mg/dL. However, the total serum calcium is often a poor indicator of the Ca²⁺ status, since abnormalities of serum protein concentrations (primarily albumin) affect the total calcium. A decrease in albumin concentration lowers the measured serum calcium, and an increase raises it, even as the Ca²⁺ level remains unchanged. A corrected serum calcium level that accounts for changes in serum albumin concentrations can be calculated as follows:

Corrected calcium = serum calcium (mg/dL)  

\[ \equiv +0.8[4 \text{– serum albumin (g/dL)}] \]

This formula is only an estimate, and the Ca²⁺ should be measured whenever hypocalcemia is suggested. Blood gas analyzers can measure Ca²⁺ from a sample of blood or serum. The normal range is 1.00 to 1.15 mmol/L.

Changes in acid-base status influence the ratio of bound to ionized calcium without altering the total measured calcium. Acidosis decreases calcium binding to albumin, and alkalosis increases binding. Thus, acute changes in blood pH may have important physiologic effects by changing the Ca²⁺ level even when the total serum calcium level remains unchanged.

## Hypocalcemia
### Principles of Disease
The causes of ionized hypocalcemia are numerous (Box 123-7) and can be divided into disorders causing PTH insufficiency, vitamin D insufficiency, PTH resistance states, and calcium chelation.

**Parathyroid Hormone Insufficiency.** PTH insufficiency can be caused by either primary or secondary hypoparathyroidism. Primary hypoparathyroidism is rare and is usually congenital. Maternal hyperparathyroidism may result in fetal parathyroid hypoplasia and transient hypoparathyroidism.

Secondary hypoparathyroidism is more common and is most often iatrogenic, resulting from inadvertent removal of the parathyroid glands or disruption of the vascular supply during parathyroid, thyroid, or carotid surgery. Permanent hypocalcemia is the usual consequence. Excision of a functional parathyroid adenoma, leaving only the chronically suppressed but otherwise unaffected parathyroid tissue, causes hypocalcemia that usually resolves over several days. Metastatic carcinoma or infiltrative disorders (e.g., hemochromatosis, sarcoidosis, Wilson’s disease) may destroy parathyroid tissue and cause hypocalcemia. Both severe hypomagnesemia and severe hypermagnesemia can impair PTH release. Drugs that may suppress parathyroid function include chemotherapeutic agents, cimetidine, and ethanol.
Hormone Resistance

Causes of Hypocalcemia

States.

Vitamin D deficiency can result in hypocalcemia. Parathyroid hormone resistance states are responsive to PTH, and phosphate retention. Generally, failure. This results from vitamin D deficiency, impaired increase in urinary cyclic adenosine monophosphate hypoparathyroidism is based on elevated PTH levels and a lack of increase in urinary cyclic adenosine monophosphate after PTH administration.

Hypocalcemia is common in patients with chronic renal failure. This results from vitamin D deficiency, impaired responsiveness to PTH, and phosphate retention. Generally, these patients are asymptomatic, possibly because of a protective effect of systemic acidosis. However, rapid correction of metabolic acidosis with exogenous sodium bicarbonate can precipitate severe hypocalcemia, often causing tetany and seizures.

Calcium Chelation. Calcium complexes with several different substances in serum, including proteins, fatty acids, and anions. Increases in the concentration of these substances may thus result in ionized hypocalcemia. Citrate is used as a blood preservative and anticoagulant. The citrate load associated with massive blood transfusion (6-8 U) causes hypocalcemia in up to 94% of patients. Hypocalcemia is usually short-lived, and Ca levels return to normal shortly after transfusion. Because citrate is metabolized by temperature-dependent enzymes in tissues and excreted by the liver, hypothermia and hepatic failure are important risk factors for protracted hypocalcemia after blood transfusion. Citrate is also a constituent of radiocontrast material, and hypocalcemia has been associated with the administration of these agents.

Exogenous administration of phosphate and endogenous hyperphosphatemia (e.g., with acute renal failure, rhabdomyolysis, or tumor lysis syndrome) are well-known causes of hypocalcemia. Exogenous bicarbonate also complexes with calcium and may cause symptomatic hypocalcemia. Alkalosis, either metabolic or respiratory, enhances the binding of calcium to serum proteins, resulting in ionized hypocalcemia. Free fatty acids liberated in various conditions (e.g., acute pancreatitis, hyperadrenergic states, acute ethanol ingestion) can chelate free Ca to form calcium soaps. Fluoride poisoning can also cause hypocalcemia. This may occur after exposure to hydrofluoric acid or ammonium bifluoride, components of many household cleaners and rust removers. These compounds release free fluoride ion, a direct cellular toxin that binds Ca, forming calcium fluoride. Numerous cases of severe hypocalcemia, cardiac dysrhythmias, and death have been reported after ingestion, inhalation, or cutaneous exposure to these products.

Clinical Features

The clinical manifestations of hypocalcemia depend not only on the serum level but also on the rapidity with which it declines. Although the signs and symptoms of hypocalcemia are numerous, the effects on neuromuscular function predominate.

A declining serum calcium level is associated with progressive neuromuscular hyperexcitability. CNS manifestations include depression, irritability, confusion, and focal or generalized seizures. Peripheral nervous system manifestations include perioral paresthesias, muscle weakness and cramps, fasciculations, and tetany. Latent tetany can often be demonstrated by eliciting Chvostek’s or Trousseau’s sign. Chvostek’s sign is elicited by tapping over the facial nerve and causing twitching of the ipsilateral facial muscles. Trousseau’s sign describes carpal spasm in response to inflation of an arm blood pressure cuff to 20 mm Hg above systolic blood pressure for 3 minutes.

Severe hypocalcemia causes a decrease in myocardial contractility and, rarely, bradycardia, hypotension, and symptomatic congestive heart failure. Patients with preexisting cardiac dysfunction and those taking digoxin or diuretics are especially at risk. The ECG may demonstrate QT prolongation, and an inverse relationship exists between the serum calcium level and the QT interval. However, the ECG is a poor predictor of hypocalcemia and should not be used to rule in or rule out this disorder.

Bronchospasm and laryngeal spasm occur rarely. Symptoms and signs ranging from anxiety and depression to psychosis and dementia can be seen.
Patients with asymptomatic hypocalcemia can be treated with oral calcium supplements. Available preparations include calcium ascorbate, calcium gluconate, and calcium lactate. Most patients require 1 to 4 g of elemental calcium daily in divided doses.

**Hypercalcemia**

**Principles of Disease**

Hypercalcemia is a relatively common medical disorder. Routine laboratory screening can be expected to detect hypercalcemia in 0.1 to 1.0% of patients, depending on the population being screened. Hypercalcemia is usually mild (<12 mg/dL) and asymptomatic and rarely requires emergency treatment. Nevertheless, hypercalcemia may be an important clue to a serious underlying medical disorder. **Hypercalcemic crisis** occurs in a subset of patients who have severe hypercalcemia (usually >14 mg/dL) and is generally associated with prominent signs and symptoms. In this situation, immediate measures to lower the serum calcium level are indicated.

Although hypercalcemia has many causes, more than 90% of cases result from primary hyperparathyroidism or malignancy (Box 123-9).

Primary hyperparathyroidism is the most common cause of hypercalcemia in outpatients, accounting for 25 to 50% of cases. This can result from parathyroid adenoma (80%), parathyroid hyperplasia (15%), or parathyroid carcinoma (5%). Hyperparathyroidism can also occur in association with other endocrine tumors as part of one of the familial syndromes of

**Management**

In patients with suggested hypocalcemia or a documented low total serum calcium level, the first step in management should be verification of true ionized hypocalcemia. When hypocalcemia is the presumed cause of tetany, seizures, hypotension, or dysrhythmias, it may be appropriate to initiate treatment before the Ca\(^{2+}\) level is available. All patients with symptomatic hypocalcemia should be treated with parenteral calcium. Two different formulations are readily available in most emergency departments: (1) 10-mL ampules of 10% calcium chloride, which contain 360 mg of elemental calcium, and (2) 10-mL ampules of 10% calcium gluconate, which contain 93 mg of elemental calcium. For the adult patient, the recommended initial dose is 100 to 300 mg of elemental calcium given as calcium chloride or calcium gluconate. This dose of calcium increases the serum Ca\(^{2+}\) level for only a short time (1–2 hours) and should be followed by repeated doses or an infusion at a rate of 0.5 to 2 mg/kg/hr. For neonates, infants, and children, the recommended initial dose is 0.5 to 1.0 mL/kg of 10% calcium gluconate over 5 minutes.

The most common side effects of IV calcium administration are hypertension, nausea, vomiting, and flushing. Bradycardia and heart block occur in rare cases. Patients receiving IV calcium should be placed on a cardiac monitor, and administration should be discontinued if bradycardia ensues. Calcium should be administered with extra caution in patients taking digoxin because it may precipitate (or exacerbate) digoxin-induced cardiotoxicity. Because calcium can cause severe tissue irritation and necrosis if it extravasates, it should always be given through a well-functioning catheter. Whenever possible, calcium chloride should be diluted in 5% dextrose in water (D\(_5\)W).

Symptoms refractory to appropriate doses of calcium may be caused by coexisting hypomagnesemia. In patients with normal renal function, administration of 2 to 4 g of 10% magnesium sulfate should be considered.

multiple endocrine adenomatosis. In primary hyperparathyroidism, the PTH level is elevated in more than 90% of cases; the remainder of patients have high-normal PTH levels that are inappropriate for the degree of hypercalcemia. An elevated PTH level leads to increased bone resorption, a relative decrease in renal calcium excretion, and increased intestinal calcium absorption. Patients typically develop hypercalcemia, phosphaturia, hypophosphatemia, and a hyperchloremic metabolic acidosis.

Malignancy is the most common cause of hypercalcemia in hospitalized patients, and hypercalcemia is the most common paraneoplastic complication of cancer. The reported prevalence of hypercalcemia in patients with cancer ranges from 15 to 60%. A multitude of solid tumors can cause hypercalcemia, including cancers of breast, lung, colon, stomach, cervix, uterus, ovary, kidney, bladder, and head and neck. Hypercalcemia is also seen with hematologic malignancies such as multiple myeloma and lymphoma. Hypercalcemia in patients with cancer can result from several different mechanisms, including production of PTH-related protein by the tumor. This polypeptide is homologous to PTH in its first 13 N-terminal amino acids and binds to the PTH receptor, mimicking all the actions of the hormone. PTH-related protein is secreted by solid malignancies and their metastases and is not subject to normal feedback control mechanisms. Assays for PTH-related protein are available to confirm this cause of cancer-related hypercalcemia. Less often, hypercalcemia results from the production of other bone-resorbing substances by the tumor (e.g., transforming growth factor-α) or the local effects of osteolytic skeletal metastasis. Virtually all patients with cancer-associated hypercalcemia have low concentrations of PTH, readily distinguishing this cause of hypercalcemia from primary hyperparathyroidism.

Thiazide diuretics are associated with up to 20% of cases of hypercalcemia. These agents can increase the reabsorption of calcium in the distal convoluted tubule by as much as 70%. Hypercalcemia is typically mild, although it may be exaggerated in patients with dehydration.

Granulomatous disorders (e.g., sarcoidosis, tuberculosis, coccidioidomycosis, histoplasmosis, leprosy) can cause hypercalcemia. In these conditions, activated macrophages convert 1,25-hydroxyvitamin D to its active form (1,25-DHCC), resulting in enhanced intestinal calcium absorption, hypercalcemia, and hypercalciuria. Certain lymphomas cause severe hypercalcemia by a similar mechanism. Interestingly, hypercalcemia in patients with sarcoidosis occurs as a seasonal event in patients who live in the Northern Hemisphere, presumably because of increased production of vitamin D in the skin during longer exposure to the summer sun.

Acute vitamin A intoxication is an uncommon but well-recognized cause of hypercalcemia, resulting from an increase in osteoclastic activity. This usually occurs after an accidental massive ingestion of a preparation containing vitamin A. Chronic hypervitaminosis A can occur in patients using large doses of the vitamin for a variety of dermatologic conditions (e.g., acne vulgaris). Because vitamin A is highly lipophilic, toxicity may take several weeks to resolve after discontinuation of the vitamin. Increased exogenous vitamin D intake may also result in hypercalcemia.

Milk-alkali syndrome is caused by excessive ingestion of calcium and absorbable antacids such as milk or calcium carbonate and is characterized by hypercalcemia, alkalosis, and renal failure. The disorder is less common since nonabsorbable antacids and H2-receptor antagonists became available for the treatment of peptic ulcer disease.

Lithium therapy for bipolar (manic-depressive) disorders can put patients at increased risk for developing hypercalcemia. Clinical and in vitro studies suggest that lithium alters the release of PTH by shifting the set point for inhibition of hormone secretion by circulating calcium.

Thyroid hormone causes hypercalcemia by increasing bone turnover through direct stimulation of osteoclastic bone resorption. In most cases, the symptoms of hyperthyroidism predominate, and hypercalcemia does not become apparent until hyperthyroidism is managed. Hypercalcemia can also be seen in patients after renal transplantation or in the early phase of acute tubular necrosis.

Clinical Features

The clinical manifestations of hypercalcemia are nonspecific and vary widely from patient to patient (Box 123-10). Severity of symptoms depends on both the level of serum calcium and the rapidity of its rise.

Hypercalcemia decreases neuronal conduction and in general causes CNS depression. Symptoms range from fatigue, weakness, and difficulty concentrating to confusion, lethargy, stupor, and even coma.

Hypercalcemia has several effects on the cardiovascular system. The volume depletion with which hypercalcemia is typically associated can result in hypotension. Because hypercalcemia causes an increase in vascular tone, however, the blood pressure may be misleadingly normal. Characteristic ECG changes include shortening of the QT interval and, to a lesser degree, prolongation of the PR interval and QRS widening. Rarely, severe hypercalcemia causes sinus bradycardia, bundle branch block, high-degree atrioventricular block, and even cardiac arrest. Calcium potentiates the action of digoxin, and the side effects of digoxin are accentuated when hypercalcemia is present.

**BOX 123-10. CLINICAL FEATURES OF HYPERCALCEMIA**

| **Neurologic** | **Fatigue, weakness** |
| **Confusion, lethargy** | **Ataxia** |
| **Coma** | **Hypotonia, diminished deep tendon reflexes** |

| **Cardiovascular** | **Hypertension** |
| **Sinus bradycardia, atrioventricular block** | **ECG abnormalities (short QT, bundle branch block)** |
| **Ventricular dysrhythmias** | **Potentiation of digoxin toxicity** |

| **Renal** | **Polyuria, polydipsia** |
| **Dehydration** | **Loss of electrolyte** |
| **Prerenal azotemia** | **Nephrolithiasis** |
| **Nephrocalcinosis** | **Gastrointestinal** |
| **Nausea, vomiting** | **Anorexia** |
| **Peptic ulcer disease** | **Pancreatitis** |
| **Constipation, ileus** | **ECG, electrocardiographic.** |
An acute rise in the serum calcium level impairs the reabsorption of fluid and electrolytes in the renal tubule, promoting the development of dehydration, which is worsened by vomiting and poor fluid intake. This may lead to a vicious cycle of volume depletion, reduced GFR and calcium excretion, intensified hypercalcemia, and further dehydration, culminating in oliguric renal failure, coma, and death. Chronically, hypercalcemia and associated volume depletion predispose the patient to renal calculi, nephrocalcinosis, and calcium-induced interstitial nephritis.

Anorexia, nausea, vomiting, and abdominal pain are common but nonspecific symptoms of hypercalcemia. Hypercalcemia decreases smooth muscle tone and may lead to constipation or intestinal ileus. An increased serum calcium level enhances the release of hydrochloric acid, gastrin, and pancreatic enzymes. Chronic hypercalcemia has been associated with an increased risk of peptic ulcer disease and pancreatitis.

Management

Treatment should be initiated at once in patients with evidence of significant dehydration, alteration of consciousness, or symptomatic dysrhythmias. Patients with severe hypercalcemia (>14 mg/dL) require rapid treatment regardless of symptoms. The four basic goals of therapy are (1) restoration of intravascular volume, (2) enhancement of renal calcium elimination, (3) reduction of osteoclastic activity, and (4) treatment of the primary disorder (Box 123-11). Although it may not be realistic to expect to achieve these goals in the emergency department, it is important for the emergency physician to initiate therapy and involve the appropriate consultants as early as possible.

**Fluid Administration.** The administration of isotonic saline is the first step in the management of severe hypercalcemia. Once the intravascular volume has been restored to normal, the serum calcium level will usually have decreased by 1.6 to 2.4 mg/dL, although hydration alone rarely leads to complete normalization. The expansion of intravascular volume increases renal calcium clearance by increasing GFR and Na⁺ delivery to the distal tubules. The rate of fluid administration should be based on the severity of hypercalcemia, the degree of dehydration, and the patient’s cardiovascular tolerance of acute volume expansion. In elderly patients and those with poor left ventricular function, central venous pressure monitoring can be used to adjust fluid administration rates. Two to 5 L per day is often required. Coexisting electrolyte deficiencies should also be corrected.

**Furosemide.** Loop diuretics such as furosemide inhibit the resorption of calcium in the thick ascending loop of Henle, increasing the calciuric effect of hydration. Volume expansion must precede the administration of furosemide, however, because the drug’s effect depends on the delivery of calcium to the distal nephron. IV doses of 10 to 40 mg every 6 to 8 hours are usually sufficient. Thiazide diuretics should not be used because they enhance distal absorption of calcium and may worsen hypercalcemia.

**Osteoclast Inhibitors.** Therapy for severe hypercalcemia should also include agents that reduce the mobilization of calcium from bone. Drugs that inhibit osteoclast-mediated bone resorption include the bisphosphonates, calcitonin, glucocorticoids, and gallium nitrate. Because these drugs are used very infrequently in the emergency department, consultation with a specialist and/or pharmacist to select the best agent and dosing strategy is advised.

The bisphosphonates act by inhibiting osteoclastic bone resorption and decreasing the viability of osteoclasts. Etidronate, pamidronate, and zoledronic acid have similar efficacy and a reasonable adverse effect profile.

Calcitonin is a naturally occurring hormone that lowers serum calcium by inhibiting osteoclastic activity. Among the anticalcemic agents available, calcitonin has the most rapid onset of action, although it causes only a modest reduction in the serum calcium level. When hypercalcemia is severe and the need to lower the serum calcium is urgent, it is reasonable to administer a dose of calcitonin in combination with a more potent agent such as a bisphosphonate.

The glucocorticoids act by inhibiting the action of vitamin D. They may be effective calcium-lowering agents in patients with hypercalcemia caused by hematologic malignancies, granulomatous disorders, or vitamin D intoxication.

**Underlying Cause.** Pharmacologic therapy does not permanently normalize the serum calcium concentration. The underlying cause of the hypercalcemia needs to be treated as well. Primary hyperparathyroidism is definitively managed by parathyroidectomy. In the hands of experienced surgeons, more than 90% of patients are cured. When hypercalcemia is caused by malignancy, treatment must be directed at the underlying tumor because normocalcemia is difficult to sustain without successful treatment of the underlying cause. Hypercalcemia caused by medication responds to discontinuation of the offending agent. Hypercalcemia caused by nonparathyroid endocrine disease responds to treatment of the underlying disorder.

**BOX 123-11  MANAGEMENT OF HYPERCALCmia**

| Restoration of intravascular volume |
| Correct dehydration with isotonic solution |
| Correct associated electrolyte abnormalities |
| Enhancement of renal calcium elimination |
| Saline diuresis |
| Loop diuretics (e.g., furosemide) |
| Avoid thiazide diuretics |
| Reduction of osteoclastic activity |
| (Consult specialist for agent selection dosing.) |
| Bisphosphonates |
| Etidronate |
| Pamidronate |
| Zoledronic acid |
| Calcitonin |
| Hydrocortisone |
| Treatment of primary disorder |
| Parathyroidectomy for hyperparathyroidism |
| Withdrawal of causative medications |
| Treatment of nonparathyroid endocrine disorders |

**MAGNESIUM**

**Normal Physiology**

Magnesium (Mg²⁺) is the second most abundant intracellular cation. It is a cofactor in hundreds of enzymatic reactions, including all those involving adenosine triphosphate (ATP). Magnesium is essential for the production and use of energy, DNA, and protein synthesis, ion channel gating, hormone receptor binding, neurotransmission, cardiac excitability, and muscle contraction.

The adult human body contains approximately 2000 mEq of magnesium. One half of total magnesium is in the mineral...
component of bone, and 40 to 50% is found in the intracellular compartment. Only 1 to 2% of the body’s magnesium is present in the extracellular fluid, so the serum magnesium level is often a poor reflection of the total magnesium content. One third of the serum magnesium is bound to albumin, with the rest in the biologically active ionized form. The normal range for serum magnesium is 1.8 to 3.0 mg/dL. A balance between gastrointestinal absorption and renal excretion maintains magnesium homeostasis.

Dietary sources of magnesium include green vegetables, meats, fish, beans, nuts, and grains. Absorption of ingested magnesium occurs in the small intestine through both active and passive transport mechanisms. In the kidney, 95% of the filtered load of magnesium is reabsorbed in the proximal tubule and loop of Henle. In deficiency states, magnesium resorption is enhanced in the distal convoluted tubule under the influence of PTH. In hypermagnesemic states, renal excretion of magnesium increases.

**Hypomagnesemia**

**Principles of Disease**

Hypomagnesemia is one of the most common electrolyte deficiencies in clinical practice. Approximately 10 to 20% of hospitalized patients and 50 to 60% of patients admitted to the intensive care unit are hypomagnesemic. Despite the high prevalence of hypomagnesemia, several factors can make the diagnosis a challenge. First, the clinical manifestations of hypomagnesemia are nonspecific, so the disorder is often overlooked. Second, the serum magnesium level is not measured as part of the “routine” electrolyte panel. Third, the serum magnesium level is an insensitive indicator of magnesium deficiency. Although a low serum magnesium level is indicative of a magnesium deficit, patients with a normal magnesium level may still have a severe deficiency. Fourth, hypomagnesemia often coexists with and may be masked by other electrolyte deficiency states.

Numerous studies have demonstrated the high prevalence of hypomagnesemia in patients with hypokalemia. Because magnesium is required for the normal functioning of the Na⁺-K⁺ ATPase pump, hypomagnesemia can result in refractory hypokalemia that is not correctable by the administration of potassium alone. Magnesium replacement enhances potassium retention and decreases the amount of supplemental potassium required to achieve a net positive balance. Magnesium is also required for the normal synthesis and release of PTH. Patients with hypomagnesemic hypercalcemia typically have inappropriately low levels of PTH and target organ resistance to the hormone, which are corrected by magnesium administration. A high prevalence of hypophosphatemia in patients who are hypomagnesemic has also been described.

Because the kidneys normally conserve magnesium efficiently, significant hypomagnesemia usually occurs only when there is renal magnesium wasting or when intestinal losses exceed dietary intake and absorption (Box 123-12). In the emergency department, hypomagnesemia is most often associated with the use of diuretics and with alcohol abuse.

**Diuretics.** Patients taking diuretics for the treatment of hypertension, congestive heart failure, or both are at significant risk for hypomagnesemia. Both the thiazide and the loop diuretics promote renal magnesium loss and may cause severe magnesium deficiency. In one study, typical diuretic doses increased urinary magnesium excretion by 25 to 50%. Some authors recommend that all patients receiving diuretics be considered candidates for magnesium supplementation. The use of a potassium-sparing diuretic in conjunction with a conventional diuretic is less likely to cause hypomagnesemia because these agents also have a magnesium-sparing effect.

**Alcoholism.** The reported prevalence of hypomagnesemia in alcoholic patients varies widely, from 30 to 80%. Hypomagnesemia in the alcoholic patient is multifactorial; potential causes include poor nutrition, increased urinary excretion, gastrointestinal losses from vomiting and diarrhea, and pancreatic insufficiency.

**Renal, Gastrointestinal, and Endocrine Disorders.** Hypomagnesemia can also result from renal magnesium wasting or from decreased production of (or end-organ responsiveness to) PTH. Magnesium wasting may be seen in some patients with post-obstructive diuresis, acute tubular necrosis, chronic glomerulonephritis, chronic pyelonephritis, or interstitial nephropathy, as well as after renal transplantation. The decreased magnesium excretion typically found with acute and chronic renal failure, however, generally results in these patients tending to be hypermagnesemic.
Gastrointestinal causes of hypomagnesemia include shortbowel syndrome, protein-calorie malnutrition, bowel fistula, continuous nasogastric suctioning, chronic diarrhea, and administration of total parenteral nutrition.\(^{58}\) Patients with acute pancreatitis typically have an intracellular magnesium deficiency despite normal serum concentrations. This is most likely in patients who are also hypocalcemic.

Hypomagnesemia is the most common electrolyte abnormality in ambulatory diabetic patients and is also a common finding in patients with DKA. Excessive urinary loss associated with glycosuria and transcellular shifts of the cation are the proposed mechanisms. The clinical consequences of magnesium deficiency include impairment of insulin secretion and peripheral insulin resistance. Hypomagnesemia also may play a role in the development of retinopathy, hypertension, and the abnormal platelet function often observed in diabetic patients. Other endocrine and metabolic causes of hypomagnesemia include primary and secondary aldosteronism, hyperthyroidism, primary hyperparathyroidism, and acute intermittent porphyria.

Pregnancy. Pregnancy is marked by a state of hypomagnesemia. Serum levels usually decline in the third trimester. Patients with preterm labor are more likely to have a significantly depressed serum magnesium level.\(^{59}\)

Drugs. Hypomagnesemia has also been associated with a number of drugs.\(^ {60}\) It can result from renal magnesium wasting (e.g., aminoglycosides, amphotericin B, cephalosporins, ticarcillin) or from transcellular magnesium shifts (e.g., ciclosporin, cyclosporine, theophylline).\(^ {61}\)

Congenital Disorders. Congenital disorders causing hypomagnesemia include primary infantile hypomagnesemia and familial hypomagnesemia. Maternal diabetes, maternal hyperparathyroidism, and maternal hypothyroidism are also associated with hypomagnesemia in the newborn.

Clinical Features

The clinical manifestations of hypomagnesemia are nonspecific and can easily be confused with those caused by other metabolic abnormalities. Symptoms are inconsistent, variable in severity, and not well correlated with a specific serum magnesium level. However, patients are usually symptomatic at serum levels of less than 1.2 mg/dL. The clinical manifestations of hypomagnesemia most likely to be prominent in the emergency setting involve the neuromuscular and cardiovascular systems.

Neuromuscular manifestations include muscle weakness, tremor, hyper-reflexia, tetany, and a positive Chvostek’s or Trousseau’s sign. CNS findings range from apathy, irritability, and dizziness to seizures, papilledema, and coma. Focal neurologic findings have also been described.

Dysrhythmia is the most common cardiovascular manifestation of hypomagnesemia. A number of studies demonstrate an increased incidence of supraventricular dysrhythmias (atrial fibrillation, multifocal atrial tachycardia, paroxysmal supraventricular tachycardia) and ventricular dysrhythmias (premature ventricular contractions, ventricular tachycardia, torsades de pointes, ventricular fibrillation) in patients who are magnesium deficient.\(^ {62}\) Patients taking diuretics for the treatment of congestive heart failure are particularly vulnerable. Digitalis-induced dysrhythmias are also more likely in the presence of hypomagnesemia. Because magnesium is an essential cofactor for the Na⁺-K⁺-ATPase pump that is inhibited by digitalis, hypomagnesemia typically worsens the manifestations of digitalis toxicity.

Hypomagnesemia has been associated with a wide range of ECG findings, including prolongation of the PR, QRS, and QT intervals; ST-T segment abnormalities; flattening and widening of the T wave; and presence of U waves. These findings, however, are nonspecific and may be at least partly caused by associated hypokalemia. Thus, the ECG should not be used to rule out magnesium disturbances.

The relationship between hypomagnesemia and ischemic heart disease is controversial. Hypomagnesemia is common in emergency department patients with chest pain and in those admitted to the coronary care unit.\(^ {62}\) Patients who have a myocardial infarction are more likely to be hypomagnesemic than those who do not. This finding has been shown to be independent of concomitant diuretic use. Serum magnesium levels decline transiently after acute myocardial infarction, increasing the risk of dysrhythmia.\(^ {63,64}\) Proposed mechanisms include transcellular shifts of the cation and chelation with free fatty acids released after acute myocardial infarction. Although several studies demonstrate a benefit of empiric magnesium administration after acute myocardial infarction, the largest trial to date, the International Study of Infarct Survival, failed to confirm a significant benefit.\(^ {65}\)

Management

Because it is often an inaccurate reflection of total magnesium stores, the serum magnesium level should not be used alone to guide therapy. However, magnesium administration is appropriate in patients with a low serum level (<1.2 mg/dL), as well as in those with a normal serum magnesium level and symptoms suggestive of hypomagnesemia. For life-threatening conditions (dysrhythmias, seizures) in which hypomagnesemia is the possible cause, parenteral magnesium should be given. In patients with normal renal function, 2 to 4 g of 50% magnesium sulfate (16.6333 mEq) is a reasonable initial dose. This should be diluted in saline or dextrose and given over 30 to 60 minutes. More rapid administration may result in venous irritation and phlebitis. Bolus administration should be avoided because this may cause bradycardia and varying degrees of heart block, as well as hypotension. Magnesium should be administered with caution, if at all, in patients with atrioventricular block or renal insufficiency. Most administered magnesium is promptly excreted in the urine. Total magnesium repletion therefore requires administration of more than a single dose, generally over days.

Several different oral magnesium formulations are available. Preparations of magnesium gluconate, magnesium carbonate, magnesium oxide, and magnesium chloride each provide different doses of elemental magnesium. Large doses of magnesium salts can cause diarrhea. Magnesium as the chloride salt or as enteric-coated tablets (e.g., Slow-Mag) is usually better tolerated.

Hypermagnesemia

Principles of Disease
